An alternative to measuring oxygen by light and dark bottle method is a method that uses radiocarbon as ^{14}C -bicarbonate as a tracer. A small but known amount of radiocarbon is introduced to a water sample and the bottle is incubated for a time period in the same manner as with the oxygen method. At termination of the incubation period, the contents of the experimental bottles are filtered. Radiocarbon retained on the filters is considered to represent inorganic carbon fixed into particulate organic matter during the experiment. Any fixed carbon that leaked into the water from algal cells can also be assessed by acidifying the filtrate under vacuum to drive residual inorganic carbon out of solution. The radioactivity of residual organic release products can then be measured. The beta particles emitted from disintegrating C-14 nuclei are detected and counted by various methods, including gas or planchet Geiger-Müller (ionization) detector, liquid scintillation, or track autoradiography.

Calculation of total carbon fixation by the C-14 method requires knowledge of the specific activity of the inorganic carbon pool and of the isotopic fractionation differences between C-12 and C-14. Specific activity is the ratio of added radioisotope activity to the mass of stable isotope that the radioisotope is intended to trace. In this method the radiocarbon traces the pool of DIC. Uptake of inorganic carbon by photosynthetic organisms involves the kinetic process of diffusion and active transport across cell membranes. In such processes there are differences in the mobility of isotopes of the same element owing to differences in molecular mass. Empirical study has demonstrated that the ratio of C-12 uptake to C-14 uptake is approximately 1.06. Accordingly, the biological fixation of inorganic carbon is calculated as

$$\begin{aligned} \text{DIC fixed} &= 1.06 \times (\text{DIC in the sampled}) \\ &\times (\text{Radiocarbon fixed}) \\ &/ (\text{Total inorganic radiocarbon added}) \quad [9] \end{aligned}$$

Both light and dark bottles are used in estimation of primary production by the C-14 method, but interpretation of results from the dark bottles are quite different from interpretations for the oxygen method. In the case of C-14, the dark bottle does not measure respiration, but rather it records the rate of nonphotosynthetic carboxylation reactions by algae and bacteria. In simultaneous comparisons between C-14 and oxygen methods, it appears that C-14 measures something intermediate between net and GPP. The reason for this is that some but not all of the carbon fixed during the experiment is preferentially respired during the incubation period.

Fluorescence Methods

Indirect methods for assessing primary production rely on the fact that photosystem pigments alternate between a ground state in which they are able to absorb excitation photons of characteristic wavelengths and an energized state in which they either transfer the excitation energy to a chemical reaction or fluoresce a photon at longer wavelength and return to their ground state. The proportion of pigments in one state or the other varies with the rate of primary production expressed per unit mass of pigment. The usual reference pigment is chlorophyll *a*, the antenna pigment present in all aerobic photoautotrophs.

Application of indirect approaches requires calibration against direct measurements of primary production. Their attraction is their potential to estimate primary production in natural communities without isolation.

Interpretation and Analysis of Primary Production Results

Rates of primary production vary with depth according to light intensity, temperature, algal biomass, and physiological state of the algae. The photosynthetically active spectrum includes light from 400 to 700 nm. Near surface, light intensities are often sufficient to saturate the antenna pigments with photons. At high light, rates of photosynthesis are limited by the rates of biochemical dark reactions, specifically the carboxylation reactions, rather than by interception of light photons. Because carboxylation is enzyme dependent, the maximum rates of carbon fixation are temperature dependent and they vary with nutritional status as well.

Light intensities diminish with depth. At low light, the rate of primary production is limited by the rate at which photons are intercepted, and carbon fixation varies directly with light intensity. Temperature variations are less important at low light because in photochemical reactions limited by interception of photons, the role of temperature-dependent enzyme kinetics is minimized.

Respiration rates vary with temperature. Near the surface, as a daily average, GPP often exceeds respiration and NPP is positive. At greater depth, however, GPP declines and a depth is reached at which NPP equals zero. This depth is termed the photosynthetic compensation depth. For purposes of predicting the physiological state and growth response of the algae, it is important to recognize that organisms in aqueous suspension rarely maintain fixed vertical positions in the water. What is most important is the integral difference

between the rates of GPP and of respiration during 24 h:

$$\int_0^{24} \int_0^{z_{\text{mix}}} \text{GPP}(z, t) - R(z, t) \, dz \, dt \quad [10]$$

where z_{mix} is the maximum depth of water involved in vertical mixing during 24 h. When the integral defined by eqn [10] is positive, net growth will occur. Seasonal variations in photo-period, water transparency, temperature, and species composition influence the components of eqn [(10)], and so the critical mixing depth for net positive algal growth varies likewise.

Secondary Production

The principle of mass and energy balance used in primary production studies can be extended to heterotrophs (Downing and Rigler, 1984). Among herbivores, predators, and detritivores, material and energy are considered commodities that continually turn over through biochemical means and by replacement of individuals within a population. Secondary production is the total growth increments over a given time interval as experienced by all individuals within a population that were alive at the beginning of the interval, whether or not they survive the complete interval. Unlike primary production, there is no distinction between gross and net production; secondary production (P) is inherently a net balance of several factors:

$$P = I - \text{Eg} - \text{Ex} - R - M - G \quad [11]$$

where I is the ingestion, Eg is the egestion of unassimilated food, Ex is the excretion, R is the respiration, M is the molts or exuvia, and G is the gametes and reproductive products such as egg yolk and spermatophore capsules.

The efficiency of energy or material transfer during secondary production is expressed by several quotients. Assimilation efficiency is the ratio of assimilation ($I - \text{Eg}$) to ingestion (I). Net growth efficiency is the ratio of growth (P) to assimilation. Gross growth efficiency is the ratio of growth (P) to ingestion (I). Ecological efficiency is sometimes defined for predator-prey trophic interactions. Ecological efficiency is the ratio of predator production to prey production.

Bioenergetic Analysis

Bioenergetic analysis places its frame of reference on individual organisms of specified size, weight, or age. When eqn [11] is applied at the individual level, the result (P) is incremental growth. The units of accounting can be total body mass, content of carbon, nitrogen, or phosphorus, or calories. Analysis is facilitated if each of the terms on the right side of eqn [11] can be expressed with reference to body mass. For example, ingestion rate may be expressed as a function of food types and availability, temperature, and body mass of the consumer. Respiration may be expressed as a function of temperature, activity level, and body mass. In this way, the incremental growth of individual organisms is linked with organism size and a set of environmental conditions. The approach can then be extended to the population level by

summing calculated growth increments across the empirical size distribution of the population.

Biomass Accrual

The standing stock biomass of a population is the sum of the weights of all individuals in the population. Changes in biomass occur owing to changes either in number (N), or mean weight (W):

$$\Delta \text{Biomass} = \Delta(N \times W) = N\Delta W + W\Delta N \quad [12]$$

Equation [12] suggests a means to calculate secondary production for populations consisting of distinct cohorts. Presence of distinct cohorts is often the case among long-lived, seasonally reproducing populations. In such cases, a survivorship chart or life table for each cohort (decreasing N vs. time) defines ΔN . A parallel chart or table reporting the average individual weights of cohort members versus age or time defines ΔW .

When cohorts cannot be distinguished, as happens with continually reproducing populations, secondary production can be calculated by summing the growth increments (Δw_i) of individual life history stages:

$$P = N_1 \Delta w_1 / T_1 + N_2 \Delta w_2 / T_2 + N_3 \Delta w_3 / T_3 + \cdots + N_k \Delta w_k + T_k \quad [13]$$

where the subscripts denote individual stages (e.g., instars) or size classes and where T_i represents the mean duration of each stage. Abundances at each stage (N_i) are considered to be the mean stage-specific abundances during the period of interest.

Birth and Death Rate Analysis

Numerical changes in populations can be represented as a simple function of population size (N):

$$dN/dt = r \times N \quad [14]$$

where r is the net intrinsic population growth rate (time^{-1}) resulting from additions and removals:

$$r = \text{Birth} - \text{Death} + \text{Immigration} - \text{Emigration} \quad [15]$$

In cases where changes owing to migration are not an issue, net population growth amounts to the balance between birthrate (b) and death rate (d):

$$r = b - d \quad [16]$$

Over short time intervals an assumption is made that birth and death rates are stationary, so that the simple integral solution to eqn [14] is

$$N(r + \Delta t) = N(t)e^{r\Delta t} \quad [17]$$

and net intrinsic population growth rate r can be calculated from population sizes at the beginning and end of any time interval Δt :

$$r = \ln[N(t + \Delta t)/N(t)]/\Delta t \quad [18]$$

To decompose the net rate r into its individual components, an independent estimate is needed for either birth or death rate.

Egg Ratio Method

The egg ratio method, pioneered by Edmondson (1974), calculates birthrate from demographic properties of populations in nature. The method is particularly successful in application to parthenogenic populations, especially to species in which females produce and brood clutches of eggs, such as among rotifers and Cladocera.

The egg ratio, E , is defined as the ratio of eggs and embryos to the sum of all postembryonic stages (juveniles and adults) in the population. From egg ratio and duration of development for the embryonic stage (D), the best estimate for population birthrate (b) is

$$b = \ln(E + 1)/D \quad [19]$$

Derivation of eqn [19] requires assumption of a stable age structure for the population, and further that all embryonic and postembryonic stages experience a common death rate (d), such that d can be calculated from r and b by difference:

$$d = b - r \quad [20]$$

These assumptions are most nearly applicable to shortlived species with abbreviated juvenile stages. Accuracy of the birthrate estimate is improved if the egg ratio is based on a census of egg stages that are in final phases of development and if the development time is correspondingly restricted in range. Most of the populations to which this analysis is applied are ectotherms, so egg development times are strong reciprocal functions of water temperature.

Instar Analysis

For populations that exhibit distinct morphological stages, such as size classes or the developmental instars of arthropods, it is possible to estimate stage-specific mortality. This method requires knowledge of the durations (T_i) of each stage including their variation with time and water temperature. The numerical change in each stage is defined as

$$dN_i/dt = N_{i-1}/T_{i-1} - N_i/T_i - d_i N_i \quad [21]$$

The first term on the right side of eqn [21] represents recruitment of new individuals into the stage or age class from the preceding stage. The second term is recruitment out of the stage, and the third term is mortality within the stage. This approach assumes a uniform age distribution within each stage. It further assumes that the calculation time step is small compared to the stage durations T_i .

Instar analysis may be combined with birthrate estimation by the egg ratio method to estimate recruitment into the youngest instar category. Addition of mass or energy information about each instar or stage permits further calculation of secondary production according to eqn [13].

Functional Type Analysis

Owing to the extraordinary phylogenetic diversity of many marine plankton communities, and a desire to develop models of entire ecosystems that can help evaluate global change, an approach has emerged that simplifies the representation of community members according to their functions, such as primary producer, herbivore, carnivore, or decomposer. These approaches diverge from those that focus on genetical entities, but they bridge the biotic world with the processes discussed in section "Biogeochemistry and Nutrient Cycling." They incorporate explicit treatment of elemental stoichiometries of the organisms and allometric variation of physiological processes with organism size or individual biomass. Application to field conditions sometimes involves the use of automated image analysis to categorize organisms and to develop size spectra of community members.

Biogeochemistry and Nutrient Cycling

Transformations of matter and energy in aquatic ecosystems are dependent on, and in turn influence, the availability of all the elemental constituents of protoplasm including both major components like carbon and nitrogen as well as trace constituents such as iron and manganese. Even elements and compounds that are not essential constituents of biological material are affected by ecosystem processes. For example, redox reactions and pH changes caused by biological reactions can influence the solubility and reactivity of metals such as mercury and cadmium, which can become toxic.

Redfield is credited with the conceptual theory of "biochemical circulation" within ocean ecosystems, and the theory is equally applicable to fresh waters. According to this view, processes of synthesis and decomposition may be separated in space and time, but they remain linked. Organic matter is generated at the ocean surface where radiant energy from sunlight permits positive net primary production. Carbon is assimilated from inorganic sources into organic form, together with nitrogen, phosphorus, silicon, iron, and all the other constituents of protoplasm. Over time, a portion of this synthesized organic matter will be transported actively or passively to deeper depths in perpetual darkness where photosynthesis is impossible. Once there, the allochthonous organic matter is used in secondary production, but its ultimate fate is to be recycled to inorganic mineral form or to be buried in sediments for long periods of geological time. Organic matter that is not transferred to the depths is recycled *in situ*, owing to the production inefficiencies of multiple secondary production pathways including herbivory, predation, and detritivory.

Physical processes of upwelling and thermohaline circulation permit some mineral nutrients dissolved in deep water to be returned to the surface for another round of synthesis reactions. Over geological time scales even the elements buried in the ocean sediments can become available again through weathering of the ancient deposits. This alternation between the inorganic state of an element and a state in which it is associated with organic processes at both biological

and geological time scales is the basis for the term biogeochemistry.

For elements such as carbon and nitrogen, organic transformations entail changes in oxidation state and allied chemical properties. For others such as phosphorus and silicon, transformations affect not oxidation state but rather solubility.

Elemental nutrients that are essential for the production of organic matter can be traced through ecosystem transformations owing to the principle of conservation of matter. Quantitative illumination of the pathways has led to production of descriptive "cycles" for each element. Different aquatic ecosystems exhibit characteristic magnitudes of different pathways. Even water itself is involved in a hydrological cycle, in which water alternates among liquid, gas, and solid phases, and among ocean, atmosphere, and terrestrial environments. Water evaporates from the sea surface to the atmosphere, from where some of it falls as rain on the continents.

Surface and groundwater on the continents react with carbon dioxide from the air and from respiration of soil biota. The resulting solution thus includes carbonic acid. In some regions the carbonic acid is supplemented by strong acids introduced by anthropogenic activities. For example, combustion of fossil fuels introduces oxides of nitrogen and sulfur into the atmosphere, because the elements were components of the ancient protoplasm that underwent diagenesis to form the fuel sources. After reacting with atmospheric water vapor, the oxides enter aqueous solution as nitric and sulfuric acids. The resulting mix of weak and strong acid is the primary agent of chemical weathering, a process that dissolves the rocks of the continents. Chemical weathering accounts for most of the ions in river water.

Elements that enter the ocean by runoff from the continents or as wind-blown dust are subject to further reactions and removal processes. Biological processes are prominent among these. Microbiological processes reduce sulfate to sulfide, followed by loss of hydrogen sulfide gas or chemical precipitation of metal sulfides. Inorganic carbon is transformed into particulate organic matter or is precipitated from solution with calcium as the skeletons of marine organisms. Silica is precipitated likewise, as cell wall covering or skeletal material for a variety of plants and animals.

Inputs of new material and removal processes are in close balance, for the bulk chemical composition of the ocean appears to be in steady state. The relationship between material flux and pool sizes in biogeochemical cycles is expressed through the concept of residence time, defined as

$$\text{Residence time (yr)} = \frac{\text{Amount of a given element in the ocean}}{\text{Rate of addition or removal per year}} \quad [22]$$

Elements that exhibit great biological reactivity, such as the nutrient elements N, P, and Si, have short residence times and are usually present at low concentrations. Elements with lower significance to biological reactions such as Na and Cl have long residence times, and correspondingly account for most of the dissolved salt in sea water.

New and Regenerated Production

In the late 1960s, Dugdale and Goering introduced a conceptual model of biological production in the surface ocean euphotic zone. The model represented the euphotic zone as a compartment or box with inputs and outputs of nitrogen. The inputs were delivered via upwelling, nitrogen-fixation of dissolved diazo-nitrogen gas, and river runoff from the continents. Outputs were the sinking material consisting of dead plankton and fecal pellets. In addition to the inputs and outputs, they described internal recycling processes within the euphotic zone, through which nitrogen was regenerated by zooplankton and bacteria.

To maintain steady state, the outputs from the euphotic zone must equal the inputs, irrespective of the magnitudes of regeneration. Dugdale and Goering reasoned that primary biological production that was sustained by the inputs, or "new" nitrogen, should be called new production, and that the primary production sustained by regenerated nitrogen should be called regenerated production. "New" nitrogen typically arrives in the form of nitrate, a form that is thermodynamically favored at the redox potential of surface sea water, and is the form to which organic matter is decomposed under aerobic conditions. "Regenerated" nitrogen is typically ammonium, which is at the same reduced oxidation state as the primary amino nitrogen that comprises proteins. Most aquatic animals are ammonotelic in their excretion metabolism. Thus, the forms of nitrogen used to support primary production of organic matter are a clue to the processes that dominate production.

The concepts were further refined by Eppley and Peterson into a modern ecosystem paradigm of biological oceanography. New production is sustained by imported nutrients. It is considered to be equal to the sum of sinking flux of organic matter plus transfers of organic matter to higher trophic levels, which may be exported from the ecosystem by, for example, fisheries yields. By empirical evidence, ecosystems dominated by "new" production exhibit higher primary production overall and are more capable of sustaining exploitation such as harvest of fisheries stocks. Ecosystems dominated by "regenerated" production cannot endure prolonged exploitation of their sustaining elements.

The concept of new production and its linkage with export production has further implications for global biogeochemical cycles and specifically for carbon dioxide levels in the global atmosphere. Organic matter that is exported from the surface ocean to the deep sea represents a sink for DIC from the surface ocean. Deficits of DIC are replenished in part by dissolution of carbon dioxide from the atmosphere. As a consequence of this linkage, the fraction of global oceanic primary production that is new production represents an upper limit to the amount of carbon that can be exported and sequestered in the deep ocean.

Techniques for measuring the rates of nutrient regeneration differ depending on whether the measurements are conducted in trophogenic regions or in tropholytic regions. In tropholytic regions, primary production is minimal and thus regeneration can be assessed by measuring the accumulation of mineral nutrients directly. In trophogenic regions, synthesis reactions dominate over regeneration, and regenerated nutrients are

quickly reassimilated. Techniques for measuring nutrient recycling under such conditions rely on assessment of uptake and regeneration simultaneously, such as by isotope dilution. In isotope dilution experiments, a deliberate tracer such as ^{15}N -ammonium is introduced to a closed system in which ^{14}N is the predominant natural isotope. Over time, the ratios of ^{15}N to ^{14}N in the ammonium pool become diluted as regenerated ^{14}N -ammonium is added, even while uptake of both isotope forms proceeds.

Stable Isotopes

Stable isotopes of natural elements are ubiquitous. They have often been collected and used as deliberate tracers, such as in studies of new and regenerated production, but they can be measured and used at natural occurrence as well (Lajtha and Michener, 1994; Griffiths, 1998). Owing to the proportions in which different nuclear species survived the first instants of the universe, and the proportions that have been retained in the planetary composition of the Earth, many common elements exhibit more than one stable form. Hydrogen, carbon, nitrogen, oxygen, and sulfur, for example, all have two or more nuclear configurations that differ in numbers of neutrons and hence differ in atomic mass. Oxygen-16, O-17, and O-18 are stable (not radioactive), but they exist in different proportions in the environment. The different forms can be distinguished by mass spectrometry. The preferred form of analysis is by isotope ratio mass spectrometer, which compares the stable isotope ratios in a sample with ratios in a standard.

Measurement of stable isotope ratios in natural materials has been a technique used by geochemists for decades to help interpret complex processes. The relative proportions of the stable isotopes vary from one medium or substance to another. Mechanisms that can change the proportions of two stable isotopes of the same element are called fractionation processes. Fractionations result from differing mobilities and reactivities by the same chemical element owing to differences in atomic mass. Both kinetic and thermodynamic factors affect the magnitudes of fractionation. Five general rules apply:

1. Elements with high atomic mass generally exhibit smaller fractionation among their isotopes than do lightweight elements.
2. If multiple isotopes of an element exist, fractionation is greatest between isotopes that have the largest atomic mass difference.
3. In unidirectional reactions, the lighter isotope becomes enriched in the endpoint.
4. In reactions that reach equilibrium, the lighter isotope is enriched in the reactant compound or phase that has the weaker bond strength.
5. As temperature increases, fractionation decreases asymptotically to zero.

Changes in the fractionation ratios with temperature have been the basis for using stable isotopes in geo-chemical studies as "paleothermometers."

Atmosphere, terrestrial, and marine environments are heavily dominated by single isotope forms of common

elements, and the alternate isotopes are usually very rare. For example, in the atmosphere, O-16, O-17, and O-18 co-occur in overall ratios by atoms as 1 : 0.0004 : 0.002. Similarly, C-12 and C-13 occur in atmospheric carbon dioxide in the mean ratio 1 : 0.011. Given such disparities of magnitude, isotope ratio differences between samples and standard are calculated in δ notation with units of parts per thousand, or per mille (‰). For example,

$$\delta - ^{18}\text{O} = \left[\left(^{18}\text{O}/^{16}\text{O} \right)_{\text{sample}} / \left(^{18}\text{O}/^{16}\text{O} \right)_{\text{standard}} - 1 \right] \times 1000 \quad [23]$$

Isotopes are useful in ecosystem studies because physical reactions and enzyme reactions cause reproducible discrimination between isotopes. Reaction differences lead to differences in the composition of biological material, skeletal products, and inorganic nutrient pools.

Stable isotopes have been used to infer and trace the origins and pathways of materials in aquatic ecosystems. They are useful when different sources are isotopically unique and when the sources change in predictable ways. Successful applications require that the magnitudes of all isotope fractionations that result from physical, chemical, and biological processes be known.

Isotopes of carbon and nitrogen have been used to trace food-web relations in freshwater and marine environments. Phytoplankton discriminate against C-13 during photosynthetic carbon fixation, just as they discriminate against C-14. The magnitude for discrimination against C-13 is less than for C-14, or about -20 to -30‰ with respect to the source DIC. Organic matter that originates from terrestrial sources sometimes has very different carbon isotope ratios than material that is of aquatic origin. Terrestrial plants fractionate atmospheric CO_2 differentially during photosynthesis according to whether they use C-3, C-4, or CAM pathways for carbon fixation. Similarly, organic matter generated microbologically from methane as a substrate typically exhibits unique carbon isotope ratios. Stable isotopes may thus be used to identify chemoautotrophic pathways as well as photoautotrophic ones.

Carbon isotopic ratios in animals resemble those of their diets within about 1‰. Slight enrichment of C-13 in an animal versus its diet is presumed to be caused by preferential loss of C-12 during respiration or by preferential assimilation of C-13 from the food. Synthesis of lipid rather than protein can also influence the isotope ratios because there are reported fractionation differences between biochemical constituents. As long as the isotope ratios in different potential food sources are well defined and consistently different, the relatively conservative levels of fractionation for carbon by trophic level can indicate whether an animal is eating its food from one source, another source, or a definable mixture of the two.

Nitrogen isotope ratios also reflect the composition of an animal's diet, but the animal is usually enriched with N-15 by about $+3\text{‰}$ compared with its food. This increased retention of N-15 over N-14 seems to be favored by the thermodynamics associated with transamination reactions, and by kinetic factors leading to preferential loss of N-14 as excreted

ammonium and urea. Reproducible differences in $\delta-^{15}\text{N}$ with trophic level provide a diagnostic measure of relative trophic position among organisms that depend on the same primary source of organic matter. Carnivores are isotopically heavier than herbivores, which in turn are isotopically heavier than the algae; omnivores are isotopically intermediate between herbivores and carnivores.

Interpretation of nitrogen isotope dynamics can be complicated by temporal and spatial variations in isotope fractionation and nutrient source materials. In laboratory experiments when nutrients are supplied in great excess of consumptive demand, isotope fractionations associated with assimilation of nitrate and of ammonium can be large. However, if a nutrient element becomes limiting and all of it is consumed, there can be no isotopic fractionation. In nature, seasonal alternation between times of nutrient excess and nutrient limitation is common, with the result that isotope ratios can vary greatly in the source material and in the primary producers. Such variations provide useful information about nutrient dynamics, but simultaneously introduce

complication to interpretations of trophic relations particularly for long-lived organisms.

Glossary

Autotroph Literally, a self-feeder; an organism that is able to utilize inorganic carbon (carbon dioxide) as the sole carbon source for growth; for example, green plants and certain bacteria.

Black box Entity that can be examined at the system level without specifying its internal contents.

Heterotrophy Literally, a feeder on others; an organism that is dependent on organic material from an external source to provide carbon for growth; for example, vertebrates.

Industrialized agriculture Modern form of agriculture that differs from traditional agriculture in the use of elaborate and expensive machinery, the control of pests with toxic chemicals rather than biocontrols, fertilization by synthetic rather than organic products, excessive

consumption of water, and farm ownership and management by corporations rather than individuals.

Input environment Collective term for all energy and materials moving into a given system.

Mega-city Modern city with a large, expanding population, characterized by high consumption levels of energy, water, and food from sources outside the city.

Output environment Collective term for all energy and materials moving out of a given system.

Techno-ecosystem Technology-based ecosystem in the contemporary world that is fundamentally distinct from natural ecosystems in the use of energy sources other than sunlight (fossil fuels, nuclear power), an urbanized concentration of human population, and the generation of substantial amounts of air and water pollutants and waste materials.

Introduction

The ecosystem is the first unit in the molecule to ecosphere hierarchy (as shown in [Figure 1](#)) that is complete, that is, it has all the components, biological and physical, necessary for survival. Accordingly, it is the basic unit around which to organize both theory and practice in ecology. Furthermore, as the shortcomings of the “piecemeal” short-term technologic and economic approaches to dealing with complex problems become ever more evident with each passing year, management at this level, that is, *ecosystem management*, emerges as the challenge for the future.

Since ecosystems are functionally open systems, consideration of both inputs and outputs is an important part of the concept, as shown in [Figure 2](#). A diversity of species and genetic forms, together with a variety of functions and niches, are essential properties of natural ecosystems. Ecosystem diversity provides redundancy in times of environmental uncertainty.

The Ecosystem Concept

The term “ecosystem” was first proposed in 1935 by the British ecologist A. G. Tansley, but of course the concept is by no means so recent. Allusions to the idea of the unity of organisms and the environment (as well as the oneness of humans and nature) can be found as far back in written history as one might care to look. Not until the late 1800s did formal statements begin to appear, interestingly enough, in a parallel manner in the American, European, and Russian ecological literature. Thus, in 1877 Karl Mobius wrote (in German)

about the community of organisms in an oyster reef as a “biocoenosis,” and in 1887 S. A. Forbes, an American, wrote his classic essay on the lake as a “microcosm.” The pioneering Russian V. V. Dokuchaev and his chief disciple, G. F. Morozov (who specialized in forest ecology), emphasized the concept of the “biocoenosis,” a term later expanded by Russian ecologists to “geobiocoenosis” ([Sukachev, 1959](#)).

In addition to biologists, physical scientists and social scientists began to consider the idea that both nature and human societies function as systems. In 1925, the physical chemist A. J. Lotka wrote in a book entitled *Elements of Physical Biology* that the organic and inorganic worlds function as a single system to such an extent that it is impossible to understand either part without understanding the whole. It is significant that a biologist (Tansley) and a physical scientist (Lotka) independently and at about the same time came up with the idea of the ecological system. Because Tansley coined the word “ecosystem” and it caught on, he gets most of the credit, which should be shared with Lotka.

In the 1930s, social scientists developed the holistic concept of regionalism, especially Howard W. Odum, who used social indicators to compare the southern region of the United States with other regions (Odum, 1936; Odum and Moore, 1938). More recently, [Machlis et al. \(1997\)](#) and Force and Maddie (1997) have promoted the idea of the human ecosystem that combines biological ecology and social theories as a basis for practical ecosystem management. Accordingly, the concept of the ecosystem now brings together organisms, the physical environment, and humans.

As shown in [Figure 2](#), a graphic model of an ecosystem can consist of a box that we can label the system, which represents the area we are interested in, and two large funnels that we can

Figure 1 Hierarchical organization of living systems. The ecosystem is the first level that is complete.

Figure 2 This ecosystem model emphasizes the external environment, which must be considered an integral part of the ecosystem concept. See **Figure 3** for a model emphasizing internal structures and processes.

label *input environment* and *output environment*. The boundary for the system can be arbitrary (whatever is convenient or of interest), delineating an area such as a block of forest or a section of beach, or it can be natural, such as the shore of a lake where the whole lake is to be the system, or ridges as boundaries of a watershed.

Energy is a necessary input. The sun is the ultimate energy source for the biosphere and directly supports most natural ecosystems within the biosphere. But there are other energy sources that may be important for many ecosystems, for example, wind, rain, water flow, or fuel (the major source for urban-industrial society). Energy also flows out of the system in the form of heat and in other transformed or processed forms such as organic matter (e.g., food and waste products) and pollutants. Water, air, and nutrients necessary for life, along with all kinds of other materials, constantly enter and leave the ecosystem. And, of course, organisms and their propagules (seeds and other reproductive stages) enter (immigrate) or leave (emigrate).

In **Figure 2** the system part of the ecosystem is shown as a “black box,” which is defined by modelers as a unit whose general role or function can be evaluated without specifying its internal contents. **Figure 3** is a graphic model of the solar-powered natural ecosystem showing internal system components and functions. The interactions of the three basic components, namely, (1) the community, (2) the flow of energy, and (3) the cycling of materials, are diagrammed in this simplified compartment model. Energy flow is one-way; some of the incoming solar energy is transformed and upgraded in quality (i.e., converted into organic matter, a more upgraded form of energy than sunlight) by the community, but most of it is degraded and passes through and out of the system as low-quality heat energy (heat sink). Energy can be stored, then “fed back,” or exported, as shown in the diagram, but it cannot be reused. In contrast with energy, materials, including the nutrients necessary for life (carbon, nitrogen, phosphorus, and so on), and water can be used over and over again. The efficiency of recycling and the magnitude of imports and exports of nutrients vary widely with the type of ecosystem.

Each “box” in **Figure 3** is given a distinctive shape that indicates its general function. Circles are renewable energy sources, bullets are autotrophs, hexagons are heterotrophs, and the round-bottomed shapes are storages (in this case of nutrients and organics). The community is depicted as a “food web” of autotrophs and heterotrophs linked together with appropriate energy flows, nutrient cycles, and storages.

Both graphic models (**Figures 2** and **3**) emphasize that a conceptually complete ecosystem includes inputs and outputs along with the system as delimited, that is, an Ecosystem = IE + S + OE (input environment + system + output environment). This scheme solves the problem of where to draw lines around an entity that one wishes to consider, because it does not matter very much how the box portion of the ecosystem is delimited. Often, natural boundaries, such as a lakeshore or forest edge, or political ones, such as city limits, make convenient boundaries, but limits can just as well be arbitrary so long as they can be accurately designated in a geometric sense. The box is not all there is to the ecosystem, because if the box were an impervious container, its living contents (lake or city) would die.

It is important to emphasize that it is the *diversity of ecosystem functions* including microbial recycling, inputs and outputs as well as habitats and human land uses that need to be maintained, not just the diversity of species or biodiversity in the narrow sense.

Figure 3 A functional diagram of a natural ecosystem, with emphasis on internal dynamics involving energy flow, material cycles, and storage (S), as well as food webs of autotrophs (A) and heterotrophs (H).

The Human-Dominated Techno-Ecosystem

Current urban-industrial society not only impacts natural life-support ecosystems in negative and sometimes positive ways, but has created entirely new arrangements that we can call *techno-ecosystems* that are competitive with and parasitic on natural ecosystems. These human-made systems involve new, powerful energy sources, technology, money, and fuel-powered cities that have little or no parallel in nature. It is imperative that techno-ecosystems interface with natural life-support ecosystems in a more positive or mutualistic manner than is now the case if our rapidly growing urban-industrial society is to survive in a finite world.

Before the industrial revolution, humans were a part of—rather than apart from—natural ecosystems. In the ecosystem model of **Figure 3**, humans functioned as top predators and omnivores (the terminal H box in the food web). Early agriculture, as is the case with traditional or preindustrial agriculture as still widely practiced in many parts of the world, was compatible with natural systems and often enriched the landscape in addition to providing food. But with the increasing use of fossil fuels and atomic fission—energy sources many times more powerful than sunlight—together with the mushrooming growth of cities and increasing use of money-based market economics as the basis for decision making, the model of **Figure 3** is no longer adequate. We need to create a new model for this techno-ecosystem, a term suggested by pioneer landscape ecologist Zev Naveh (1982).

Figure 4 is our graphic model for these new (in terms of human history) fuel-powered systems. It includes the four components listed earlier: powerful energy sources, technology, money, and cities. The model shows the inputs of the new fuel energy sources and natural resources, and the increasing outputs of air, water, and solid waste pollution that are very much larger and more toxic than anything that comes out of natural ecosystems. In **Figure 5** we add to the techno-ecosystem model some natural ecosystems that provide life-supporting goods and services (breathing, drinking, and eating!) and that maintain homeorhetic (i.e., pulsing) global balances in the atmosphere, soils, freshwater, and oceans. Note that money circulates as a two-way flow between society and human-made systems, but not natural systems, thereby creating a vast market failure when society fails to pay for ecosystem services.

A modern city,¹ of course, is the major component of the fabricated techno-ecosystem. It is a very energetic hot spot that requires a large area of low-energy natural and seminatural countryside to maintain it. Current cities clean and recycle no air and or water (to the point of being redrinkable), grow little or no food, and generate a huge waste stream that impacts wide areas of downstream rural landscapes and oceans. The city does export money that pays for some natural resources,

¹The term “city” is used synonymously with the geographers’ term “standard metropolitan district (SMD)” which includes industrial areas and residential suburbs that often extend far beyond official city limits.

Figure 4 A human-dominated techno-ecosystem.

Figure 5 A human-dominated techno-ecosystem and natural ecosystem.

and the city provides many desirable cultural institutions, such as museums and symphonies, that are not available in rural areas.

In summary, cities are essentially parasites on the low-energy countryside. To call a city a parasite is not to belittle it, but to be realistic. In undisturbed nature, parasites and hosts tend to coevolve for coexistence; otherwise, if the parasite takes too much from its host, both die if the parasite has only one host. Currently humans have only one habitable host—the earth.

Especially threatening to the global life-support ecosystems is the explosive growth of *mega-cities* in the less-developed nations, caused in part by the increasing dominance of another techno-ecosystem, that of *industrialized agriculture*, with its often excessive consumption of water and use of toxic and enriching chemicals. These systems produce more food products per unit of space, but in turn are prodigious polluters and by their economic might drive small farmers out of business worldwide, forcing them into cities that are unable to assimilate them. This current situation illustrates what engineer and former president of MIT Paul Gray (1989) has written: “A paradox of our time is the mixed blessing of almost every technological development.” In other words, technology has its destructive as well as beneficial side. To bring the natural and technical ecosystems into a mutualist relationship will be society’s greatest challenge in the twenty-first century.

Glossary

Caatinga Collective name assigned to the semiarid ecosystem of eastern South America. Some authors use this term as a general name for a type of thin Amazonian forests. In this article, however, the term is reserved for the xeric caatinga region of northeastern Brazil.

Cerrado Name assigned by phytogeographers to the tropical savannas of the central Brazilian shield. Cerrado vegetation is further divided into four categories: (1) campo limpo (i.e., clean field), (2) campo sujo (i.e., dirty field or grasslands with scattered shrubs), (3) campo cerrado (i.e., closed fields or grasslands with numerous trees and shrubs), and (4) cerradao (i.e., when the vegetation is dominated by a closed canopy of trees).

Chaco Region located between the Paraná basin, the central Brazilian shield, and the Andes. The ecosystems present in the Chaco region include temperate grasslands, savannas, and arid and semiarid environments.

Llanos Region of tropical South America, in the east side of the Andean range of Colombia and Venezuela. The llanos landscapes occupy lower elevations (2–300 m), and the landforms vary from flat to rolling terrain. The dominant

vegetation is savanna with areas of dry forest, gallery forest, and morichales.

Mangal/mangle Name assigned to the vegetation of mangrove ecosystems.

Pampa(s) Region of temperate South America, west of the Andes in Argentina. The Pampa region contains several ecosystem types, including temperate grasslands, dry forest, and xeric shrub lands.

Pantanal Largest wetland of South America drained by the Paraguay River and its tributaries.

Paramo Ecosystem of the high Neotropical mountains, found in South America above tree line in the northern Andean mountains of Colombia, Venezuela, Ecuador, Peru, and Bolivia. The dominant vegetation is similar to an alpine meadow or grassland; cacti and giant-rosette plants are conspicuous.

Puna Ecosystem of the high Andean mountains found above tree line from Bolivia to southern Peru. The Puna comprises of four distinct ecological regions: wet, dry, thorny, and desert Puna. The dominant vegetation types vary from grassland/shrub lands to desert.

Varzea Floodplain of the whitewater rivers of the Amazon basin.

Outline

South America contains a diversity of ecosystems from tropical, subtropical, alpine, and temperate environments (Archibold, 1995). The geology, climate, and biogeographical history of the continent have important consequences in shaping the contemporary geographic distribution of ecosystem types and their structural attributes and functioning (Beard, 1955). The stability of the old Precambrian shields and the recent orogenic evolution of the Andean range have been the principal factors that determine geomorphologic, edaphic, and continental climatic patterns that correlate with the geographic distribution of major ecosystem types. The lifting Andean range causes altitudinal zoning and different environments that have significantly increased the diversity of ecosystems that occur in the continent. Most of the area of South America occupies tropical latitudes, hence tropical ecosystems dominate the landscapes. The main tropical ecosystems include tropical rain forest, dry forest, cloud forest, savannas, shrub lands, xeric formations, and high Andean ecosystems (Archibold, 1995). Ecosystems of the southern temperate regions include temperate grasslands, the Mediterranean Matorral, and temperate forest and deserts. There are extensive wetland ecosystems across the continent occupying areas along the floodplains of major rivers, lakes, estuarine

areas, and seasonally flooded savannas. Mangrove ecosystems occur along the tropical coastlines of both the Atlantic and Pacific oceans.

Physical Environment

South America occupies an area of approximately 18 million square kilometers and extends from about 11° N to 56° S, and from about 35° W to 81° W. The continent has been connected to Central and North America by the land bridge of the Panamanian Isthmus for approximately 3.5 million years and is bounded on the east by the Pacific Ocean, on the north by the Caribbean Sea, and on the west by the Atlantic Ocean.

Geology and Geomorphology

The geological history of South America cannot be fully covered in this summary as it is very complex and reflects many tectonic and orogenic processes operating over millions of years. However, the structural characteristics of South American ecosystems – in particular the development, properties, and geography of their soils – are significantly associated with the geophysical environment. Likewise, the major landforms

of the continent create distinctive regional climatic patterns, which ultimately affect the functioning of ecosystems. A general overview of the geology and physiography of the continent will help to explain the distribution and general properties of its major ecosystems.

The basic geomorphic features of South America are (1) the high Andean Mountain chain on the western border of the continent spreading from Venezuela to Chile, (2) the low plains of the piedmont that occupy the eastern side of the Andes, (3) the very large sedimentary lowlands of the Amazon valley, and (4) the continental shields outcropping on the east (Figure 1). These major geotectonic categories of the continent have important differences in the origin, thickness, and stage of weathering and composition of the underlying materials, which are of essential importance to determine the type, depth, and physical composition of soils. Geomorphologic processes such as soil formation and erosion have produced characteristic surface features, which identify

discrete areas developed under different climatic conditions (Harrington, 1973).

The central and eastern parts of the continent are made of three cratonic areas: the Guyana Shield, the central Brazilian Shield, and the Coastal Brazilian Shield (Figure 1). These cratonic areas have not been geologically disturbed since the Silurian ($\sim 408.5 \times 10^6$ years ago). Large plateaus and rolling highlands occupy the most eastern part of the continent covering most of the Guyana and Brazilian shields. From remote geological times, in the east side the stable Precambrian shields of the continent have held positions above sea level and have been affected by simple deformations. Landscapes in these areas, therefore, have evolved continuously under conditions of direct exposure to the atmosphere, resulting in the widespread development of old erosion surfaces. The shields consist primarily of crystalline basement complexes from the Precambrian period and the dominant rocks are granites, gneisses, and mica schists. The waste mantle can be very thick

Figure 1 Major geotectonic components of South America. 1 = Andean Belt; 2 = Amazon Basin; 3 = Central Brazilian Shield; 4 = Guyana Shield; 5 = Coastal Brazilian Shield; 6 = Llanos; 7 = Parnaíba Basin; 8 = São Francisco Basin; 9 = Paraná Basin; 10 = Chaco; 11 = Pampas; 12 = Pampean Massif; 13 = Patagonian Massif; 14 = Deseado Massif; 15 = Lowlands of Iquitos, Acre, and El Beni.

on the old erosion surfaces of the shields. The materials originated from these rocks are at an advanced stage of *in situ* weathering and are millions of years old. A shallower layer of waste material covers the landscapes of residual relief. The valley bottoms and lowlands are covered with drift material that can reach considerable depths.

Along the Andean belt (Figure 1) there are Precambrian rocks masked by different younger deposits. Since the Paleozoic, the ocean has invaded pre-Andean areas several times, and extensive marine deposits mixed with metamorphic and intrusive rocks occur all along the range from Venezuela to Chile. One important consequence of marine transgressions (i.e., ingressions and regressions) is the inland deposition of rich marine sediments. During marine regressions, erosion increased the loss of previously deposited layers. In the Early Devonian ($408\text{--}362 \times 10^6$ years ago), the largest of all marine transgressions covered the Amazon and Parnaíba basins (Figure 1), which remained submerged until the middle Devonian. In the upper Paleozoic ($290\text{--}245 \times 10^6$ years ago) only the Parnaíba basin received mixed marine and continental sediments. In the Early Mesozoic ($245 \sim \times 10^6$ years ago), eolian and fluvial sediments were deposited in the Parnaíba and Amazon basins. The Triassic sediments ($208 \sim \times 10^6$ years ago) came from continental areas and were deposited in an arid environment. During the Jurassic ($208\text{--}145 \times \sim 10^6$ years ago), the products of major volcanic activity in central and western Argentina were deposited in the Paraná, São Francisco, Parnaíba, and Amazon basins (Figure 1). During the Late Cretaceous, marine depositions also occurred over large areas of eastern South America (Harrington, 1973).

Most of the current physical features of South America – topography, coastline, and river systems – developed toward the end of the Tertiary period during the Pliocene ($2\text{--}8 \times \sim 10^6$ years ago) when the major uplift of the Andes took place. During the Tertiary, several tectonic movements accompanied by acid intrusions and volcanic activity lifted the western part of the continent forming what is now Andean Cordillera (Figure 1). During the uplifting, continuous sedimentation occurred in the inter-Andean valleys and along the eastern piedmont, forming deposits that were later involved in Andean orogenic movements that resulted in complex folded geological sequences. During the Miocene–Pliocene, most of the northern Andean ranges were strongly lifted while the southern Pampas were broken into faulted blocks. These movements were accompanied by intense volcanic activity in Colombia, Ecuador, Peru, Bolivia, Argentina, and Chile, which also cause the uplifting of the Brazilian and Guianan highlands in the eastern part of the continent. These orogenic and volcanic activities continue today, particularly in Colombia, Ecuador, and Chile, and the areas affected have very fertile soils. At present, the Andean mountains have fluctuating altitudes from 3000 to 5000 m with higher summits between Ecuador and Central Chile and the highest peak of the Western Hemisphere – Cerro Aconcagua – reaching an altitude of 7005 m in Argentina. Owing to the position of the Andes, most of the hydrological networks of the continent drain westward to the Atlantic Ocean via three main river systems: the Amazon River, the Paraná–Paraguay Rivers, and the Orinoco River.

A wide belt of low sedimentary plains extends along the eastern piedmont of the Andes, from the Llanos of Colombia

and Venezuela to the Argentinean Pampas, and eastward along the valley of the Amazon River (Figure 1). The majority of these plains reach altitudes from 200 to 500 m. These plains are composed of Tertiary and Quaternary sediments deposited from the South American and Brazilian shields and more recently from the Andes (Harrington, 1973). The intercratonic lowlands of the Amazon basin are made of heavy sedimentary clays originated from erosion of uplifted deposits washed from the Andes (Figure 1). Those deep clay sediments were deposited on the flat bottom of an ancient inland sea that covered most of the basin during the Late Tertiary–Early Pleistocene when the ocean level was higher.

Climate

Climate is an important factor that determines to some degree the type of soils and vegetation of any given region and, therefore, influences the structure and functioning of ecosystems. Figure 2 illustrates the major South American climate types according to the classification of Köppen. The shape of South America essentially determines its large-scale climatic patterns, which in turn influence the geographical distribution of ecosystems. South America has the shape of an acute triangle with most of its area situated in tropical latitudes and its southern portion extending well into high latitudes. Although the southern portion of South America reaches more than 20° farther South than the tip of Africa, the continent is so narrow at the southern end that the landmass of this region rather constitutes a continental peninsula. Because most of South America occupies tropical regions and the continental area decreases at higher latitudes, the property of climatic continentality is absent. Accordingly, the more important factors that determine the diversity of climatic regimes observed across South America are the major global atmospheric circulation patterns, the proximity to oceans and their currents, the Andean relief, and other coastal and inland topographic variations (Colinvaux, 1989).

In general, tropical temperatures dominate the northern part of the continent, declining smoothly toward the south. Major variations in temperature are due to the Andean Mountains and ocean currents. The presence of the Andes causes climatic diversity over the continent due to altitudinal variations that change wind circulation patterns and to adiabatic responses of air masses along the altitudinal gradients of the mountain chains. South American environments can range from hot deserts and warm rainy climates in the lowlands to cold deserts, temperate, and iced polar climates in the Andean highlands (Figure 2). Two ocean currents are particularly important to the regional temperatures: the cold Humboldt Current that brings lower temperatures from the south up north along the West Coast and the warm Brazilian current that brings warmer temperatures down south along the eastern part of the continent (Edit, 1968).

Owing to the lack of continentality, the distinct climates of South America are often characterized by differences in precipitation. Rainfall across most of the northern and central parts of the continent depends on the intertropical convergence (ITC). The ITC occupies its most northerly position from June to September, when it is located between 7° and 9° N. Its advance and retreat migration does not take place

Figure 2 Broad climatic regions of South America defined according to the Köppen classification system.

parallel to the equatorial line. When the ITC drifts south, a prevalent High Pressure Cell in the Atlantic Ocean restrains its movement in the eastern part of the continent causing an arch of precipitation that reaches southeast Brazil in February–March, while dry conditions persist in the northeast. This Atlantic high cell also causes higher precipitation in most of the East Coast north of Patagonia.

The Andean chain also has a significant effect on continental patterns of precipitation. Owing to adiabatic cooling, the Andean windward slopes remove moisture from the air masses moving from the Pacific causing a large rain shadow that extends from east of the Andes from Bolivia to Tierra del Fuego (Figure 2). Conversely, in the windward slopes of the Pacific coasts of Colombia and Chile, the Andes cause exceptional orographic rainfall levels, which in the Choco region of Colombia can surpass 10,000 mm per year (Figure 2). A similar effect is observed in the eastern Andean slopes of central South America where along the western edge of the Amazon basin,

moist winds rise and deliver higher precipitation levels than those registered in lower elevations of the basin. In the north of Venezuela, the northern Andean ranges block the easterly trade winds and create a tropical savanna climate that extends from northern Colombia to Surinam (Figure 2). In the western coast of the continent, between 27° and 10° S, the edge of the western Pacific high-pressure cell combined with the cold Humboldt current to produce an arid zone called, in Chile, the Atacama Desert (Figure 2). The structural complexity of the Andean relief includes inter-Andean cordilleras and valleys (e.g., the Eastern, Central, and Western Colombian cordilleras) and high plateaus (e.g., the Altiplanos of Peru and Bolivia) that further create many local climates according to variations in wind exposure and altitude (Edit, 1968).

Other extra-Andean topographic features that produce orographic climatic modifications of rain shadows or rainfalls are the highlands of the Brazilian shield that block onshore winds between Porto Alegre and Bahia; the uplands of

northeast Brazil that cause a dry rain shadow in the interior northeast region; the Guyana Highlands that block the trade winds and cause a dry winter effect in their leeward slopes; and the Sierras de Cordoba and Patagonian Plateau in Argentina, which affect air temperature and can collect moisture from humid air masses crossing Patagonia (Figure 2). There are also dry inter-Andean valleys localized along its range.

Biogeography

Early History and Associations

Biogeographers include central and northern South America in the Neotropical Kingdom, which also contains the Antilles and most of tropical Central America. Until approximately the Early Cretaceous, South America, Africa, Australia, and Antarctica were joined together composing the supercontinent Gondwanaland, thus allowing for a continuous interchange of their ancient biotas. Africa and South America share many plant families like Annonaceae, Myristicaceae, Cecropiaceae, Sterculiaceae, and Bombacaceae. Some plant genera are very diverse in one continent and barely represented on the other, for instance, *Mayaca* (about eight species in America and one in Africa), *Duvernoya* (~35 species in Africa and three in America), and *Hyptis* (~400 species in America and two in Africa). The southern cone of South America is included within the Holantartic Kingdom, which includes the temperate mesic-adapted floras of southern South America, New Zealand, and southwestern Australia. The genera of trees *Araucaria*, *Podocarpus*, and *Nothofagus* are typical although not exclusive to the southern cone. Fossil records have also shown strong ancient faunal associations between South America, Africa, Antarctica, and Australia. For instance, some of the existing species of fishes of South America, as well as their parasites, show affinities with African groups. There are also close phylogenetic relations among groups of South American, African, and New Zealand invertebrates including, among others, arachnids and mollusks.

After the separation of South America from the rest of Gondwanaland in the Early Cretaceous, the biota of the continent was isolated for millions of years. Because of their isolation, South American flora and fauna are extraordinarily rich in endemic groups and species. It is estimated that about 7% of the total world's superior plants are endemic species from Brazil, 6.8% from Colombia, 3.2% from Venezuela, 2.1% from Peru, and 2% from Ecuador. Brazil is the country with more mammal species reported in the world (>520 of which more than 130 are endemic), Colombia the fourth (>455), and Peru the ninth (>345 of which 46 are endemic). Endemic faunal families include the armadillos *Dasypodidae*, the anteaters *Myrmecophagidae*, and the monkeys *Cebidae*. Particularly important are the marsupials that in South America are represented by two genera, two families, and 87 species. There are no fewer than 3000 bird species with two orders and 30 endemic families. The humming birds, which are endemic of the New World, have more than 250 species in South America and populate ecosystems from the Amazonian lowlands to the high Andean Mountains. The diversity of endemic reptiles is exceptional; there are 520 endemic species

reported for Colombia, 468 in Brazil, 374 in Ecuador, 298 in Peru, and 293 in Venezuela, including species of snakes, turtles, and iguanas –which other than in South America only occur in the Fiji and Tonga Islands of the Pacific. Brazil is also considered as the country with highest diversity of freshwater fish species in the world with >3000 species reported, Colombia the second (>1500), Venezuela the fourth (>1200), and Peru the seventh (>850). The diversity of invertebrates is also outstanding; for example, there are more than 350 endemic species of butterflies reported for Peru, 300 for Colombia, 200 for Brazil, and 200 for Bolivia.

Late Tertiary

Although it is likely that some exchange occurred between North and South America during the Eocene and Miocene, the land bridge of the Panama Isthmus connected permanently South, Central, and North America about 3.5 million years ago. The completion of the Panamanian land bridge in the Early Pliocene was perhaps one of the most influential biogeographical events that has occurred in the continent and it dramatically changed the ancient biota of South America. The significant exchange of South and North American biotas is called by biogeographers as "the great American Interchange". Among the many invaders that entered South America through the isthmus are rattlesnakes, rodents, tapirs, deer, peccaries, felids (including jaguars and pumas), canids, and humans. About 40% of the mammal fauna of South America are species that arrived since the Pliocene. Among the South American forms that migrated to North America are the ground sloth, which disappeared about 10,000 years ago, and opossums and armadillos, which are still expanding their range. The dynamic interchange of plant and animal forms between South and North America continues at present.

Quaternary

During the past 2 million years, climatic fluctuations of dry glacial and wet interglacial periods affected the geographic ranges of both temperate and tropical areas. Palynological sequences indicate that at least during the Pleistocene, major climatic changes affected speciation and biogeographic patterns in South America. The modern geographical distributions of many endemic taxa resulted from Quaternary speciation and redistribution of species overlaid with previously existing range patterns. The explicit mechanisms that generated current biogeographical patterns are not fully understood, in part due to their inherently historical nature that is difficult to reconstruct (Bush, 1994, 2003).

Paleoecological studies initially assumed that the richness and complexity of plant communities were a consequence of continuous favorable growing conditions persisting over long time periods. Many areas have been identified as centers of endemism and proposed as tropical forest refugia occurring during the period spanning 18,000 to 13,000 years ago (Haffer, 1969). According to this hypothesis, during the last four glaciating cycles of the Pleistocene, tropical forest contracted during dry glacial periods causing most of the Amazon Basin, as well as other forested areas, to be occupied by savanna vegetation. Continuous but isolated islands of forest

(refugia) might have contained populations of plant and animal species that underwent speciation while they remained isolated. During mesic interglacial periods similar to currently existing conditions, the forest expanded again and new geographic patterns appeared including the signal of speciation processes that occurred within the refugia themselves. Paleocological data have also shown that in the Andes, the tree line has migrated down and up-slope by as much as 1500 m, matching the frequency of each northern hemispheric ice age. The estimated cooling experienced during the glacial maxima at the Sabana de Bogota is 7–9 °C. A consequence of the lowering of the tree line would be the connection of some of the high Andean Paramo ecosystems, which are currently isolated on top of mountains.

An alternative explanation for the distribution of centers of endemism proposes changes in temperature rather than precipitation as the driving force of vegetation rearrangements during glacial periods. It has been proposed that the areas of refugia were not isolated islands of stability but rather of maximal disturbance due to cooler glacial temperatures, reduced atmospheric CO₂, and moderate reductions of precipitation. Far from being static places of refuge, under this hypothesis the regions of endemism would be the dynamic edges between the forest below and the cool-tolerant vegetation above (Colinvaux, 1989).

The uplifting of the Andes during the Quaternary has also contributed to the isolation or dispersal of some taxa. While the mountain range has served as a dispersal corridor from north to south, it also represents a dispersal barrier (like the Atacama Desert) to some plants and animals. For instance, the floristic individuality of the High Andean deserts is attributed to the short history of these environments that appeared after the recent and fast uplifting of the cordillera. The age of these ecosystems might have not allowed enough evolutionary time for many species to adapt and disperse under those new conditions. There is evidence also that during interglacial dry periods the southern Andes cone experienced a cold and arid climate that served as an effective dispersal obstacle for rodents and plant species from the northern arid ecosystems.

Not only long-term events like Pleistocene glaciations or orogenic processes such as the uplifting of the Andes have had significant effects on the ecosystems of South America, but short-term climatic episodes like El Niño cause important also impacts as well. For example, changes in water temperatures of the western Pacific during El Niño years trigger profound modifications in rainfall patterns across all of South America. Major large-scale ecosystem disturbances have been associated with El Niño: fires in savannas and forests of Amazonia; droughts in the llanos of northern South America, in the Chaco region and in northeastern Brazil; and floods in Peru, Ecuador, and Colombia. There is evidence that these perturbations affect the dynamics of populations and ecosystems, which over evolutionary time could modify the composition and geographic patterns of their biota (Hooen *et al.*, 2010).

Major Ecosystems of South America

Although it is possible to make some generalizations about the nature of the biomes of the continent and their major

ecosystem types, it is important to bear in mind that across several spatial scales they are in fact complex mosaics of microhabitats (Beard, 1955). The categories of ecosystem types applied in this summary are very broad and based on the classification system developed by FAO-Unesco (1971), satellite-based maps and the ecoregions study of the World Bank/World Wildlife Fund (Dinerstein *et al.*, 1995). In this review, very general categories are used and ecosystems are geographically delimited based on broad vegetation formations (Beard, 1955). Only some key features of these major ecosystem types are briefly discussed.

Tropical Forest

Tropical forests are among the most complex ecological communities of the world and offer a variety of habitats that support an immense diversity of plants and animals (Leigh, 1975; Terborgh, 1992). South America contains more than 40% of the tropical forest of the world.

Distribution and Structure

Tropical Rain Forest

Tropical wet forests occupy the drainage of the Amazon and southern Orinoco basin, the piedmont of the Andes in northern and western South America, the Choco-Darien region between the Andes and the Pacific Ocean in western Colombia, and the southwest and Atlantic coast of Brazil (Figure 3). Among other types of tropical rain forests are Babassu palm forests, which occupy the southeastern border of Amazonia, and the liana forests, which are found in southern Amazonia between the rivers Xingu, Tapajos, and Tocantins. A liana forest is an open forest with well-spaced trees, rich in woody climbers, and often completely entwined by lianas. It occurs on all soil types, but there are no detailed studies of this vegetation, nor explanation of the factors that cause its wide distribution.

Tropical Semideciduous and Dry Forests

These ecosystems occupy part of the eastern edge of the Andes in Bolivia and Brazil, the inter-Andean valleys of Colombia, the northern edge of the Venezuelan Llanos, and the western regions of Ecuador and Peru (Figure 3). Most of the South American regions originally covered by dry forests are today populated areas, and much of the primary vegetation has been cleared. Tropical semideciduous forests usually occur on alluvial lowlands, submontane, and mountain terrains up to 1000 m. Between the Amazonian rain forest and the *Cerrado* (discussed later) of central Brazil, there is a so-called *transition forest*, which comprises a large number of plant communities. Transition forests are generally less species-rich than the moister forest in terms of plant and vertebrate species; however, plant physiognomy diversity seems to be greater in dry than in wet forests. Both transition dry forest and savannas can be found under similar climatic conditions (Beard, 1955). In eastern South America, transition forests run along most of the boundary between Amazonia and the Guyana and Brazilian shields, and they vary in width from a few kilometers to more than 100 km in some areas. The transition forest is taller and with a more closed canopy than the closed *Cerrado*, *cerradao*

Figure 3 Simplified map of the major ecosystem types of South America geographically defined on the basis of dominant vegetation.

(discussed later), but is lower and with a more open canopy than the typical Amazonian rain forests.

Mountain Cloud Forests

These ecosystems occur in the humid tropical slopes of the Andes from Venezuela to northwest Argentina and in the Santa Marta Massif in Colombia. They occupy defined altitudinal belts with the lower belts intermixing with lowland forests and the upper belts limiting with the high Andean grasslands at the tree line about 3000 m above sea level. Fog is persistent in these ecosystems and the vegetation is luxuriant with an extraordinary variety and abundance of epiphytic forms and mosses.

General Patterns

Structural variations between tropical forests are mainly governed by differences in the amount and seasonality of precipitation and the temperature regimes. In general, the

proportion of deciduous woody components increases along a gradient of rainfall, as the amount of annual precipitation decreases below 2000 mm. Although exact boundaries between ecosystems are somewhat arbitrary – because vegetation is not always so sharply delimited – the transition from arid types to rain forest seems to be primarily determined by continental climatic patterns, especially rainfall intensity and seasonality. When nonevergreen trees are present in wet tropical forests, they never shed all their foliage at the same time. A large number of woody species, of which most have evergreen foliage, characterize these ecosystems and the most frequent tree species rarely represent more than 15% of all the species present.

In general, tropical forests have a vertical structure with several strata where the tallest trees form a discontinuous layer of emergent individuals, which in South America can reach heights of 30–40 m. A denser canopy grows below and consists of two or more layers of shorter trees, small palms, tall

herbs, ferns, and shrubs. Lowland forest trees are generally shallow rooted and many of them develop buttresses at the base of their trunks, an adaptation thought to provide mechanical support. The epiphytes and vines are conspicuous in tropical forests, where the epiphytic Orchidaceae and Bromeliaceae are usually prominent. The barks of lowland tropical rain forest trees are usually thin and smooth, and this morphological characteristic makes the anchorage of epiphytic forms difficult. In the Andean cloud forests, the heights of trees decrease at increased altitudes and their shapes become irregular (e.g., elfin forest). In cloud forests, the bark of trees and the forest floor are covered with mosses, lichens, and ferns, and the diversity of fungi, algae, bryophytes, and seedless vascular plants is remarkable.

Functional Aspects

Tropical Rain Forests

A mean monthly temperature of $>26^{\circ}\text{C}$ and mean annual rainfall usually exceeding 1800 mm characterizes the Tropical Rain Forest (Af) climate that coincides with the geographic distribution of tropical rain forest (Figures 2 and 3). Some areas of tropical rain forests are the result of orographic precipitation. Isolated mountains (e.g., Sierra Nevada de Santa Marta in Colombia) or coastal escarpments (e.g., the Atlantic Brazilian Shield and the lower slopes of the Andes in the Pacific coast of Colombia and Ecuador) act as barriers to airflow, forcing moist air to ascend upslopes where adiabatic cooling generates clouds and precipitation (Terborgh, 1992). These geophysical conditions conduce to forested landscapes with a physiognomy similar to the Amazon wet evergreen forest. In areas of lowland tropical forest (e.g., Amazonia), minimum changes in temperature between summer and winter and continuous heating coupled with the high evapotranspiration rates of vegetation create a predictable pattern of daily convective rain that falls during the middle afternoon. It is estimated that up to 80% of the precipitation falling in Amazonia is retained within the hydrological cycle of the basin.

The geological material underlying the hydrographic network also influences the development of forest ecosystems. In the Amazon lowlands, large areas of forest are subject to inundation (varzea) and these ecosystems differ from those that occupy high terrain (terra firme). Rivers running from the Andes carry large amounts of silt and have a light brown color (whitewater). These large loads of silt are deposited in areas of low relief and form broad floodplains of high fertility. During the flooding season, these areas remain under several meters of water. In contrast, rivers running through the old Precambrian Shield are poor in nutrients and minerals and their waters are clear. The Shields have been exposed to millions of years of leaching and in order to conserve nutrients, plants protect their foliage with tannins. The tannins leached into the rivers give a tainted coloration to the water (blackwater). The Rio Negro and other blackwater rivers also have floodplains, but they are different because of the lack of sediments and because plant communities are adapted to acidic conditions (igapo).

Because of the high temperatures and abundant rainfall of tropical forest ecosystems, there is intense chemical action on bedrock, and soils and all soluble components continuously

leach, producing characteristic Ultisol and Oxisol soils (Terborgh, 1992). These soils are rich in iron, manganese, and aluminum, which stay behind after all other soil soluble constituents have been leached. Large amounts of these minerals arrange in stratified layers forming laterites.

Field studies have shown that tropical forests exploit a larger volume of soil than previously thought. Soil depth is therefore quite important in water balance variability because it allows evergreen forest to keep evapotranspiring during dry periods by absorbing water from soil depths of more than 8 m. Although the most rapid changes in water availability take place at the soil surface, where it is depleted by plants, the process of hydraulic lift can take water from deep soil layers and discharge it into the dryer upper layers. During the day, the water potential (ψ) gradient causes water to move from the ground into the roots, shoots, and through stomata to the atmosphere. During the night when stomata are closed, ψ in the plant equals ψ in the deep soil and a water potential gradient can move water from the deeper moist soil and plant interior into the dryer upper soil layers.

Decomposition and nutrient dynamics proceed rapidly under the warm, moist conditions of tropical forest ecosystems. High temperatures also favor an intense bacterial activity on upper soil layers and therefore there is no accumulation of humus. Many nutrients are stored in the forest biomass where they are kept from leaching. Nutrients are partitioned in different compartments of the forest and, on a weight basis, leaves contain the highest concentrations. Most of the phosphorous is stored in the leafy biomass and potassium and calcium in stem tissues. Nutrient losses in intact forests are generally low because of the high concentration of roots in the upper soil layers. The presence of mycorrhizal associations in roots enhances their nutrient uptake. Epiphytes also reduce the loss of nutrients washed away from standing biomass. Over long successional periods, the forest biomass is progressively stored in the woody components and nutrient accumulation in leaves decreases.

Invertebrates can account for up to 60% of the animal biomass of tropical forest ecosystems. About 19% of the woody fraction of the biomass is consumed by termites, beetles, and the larvae of insects. Litter is the main source of food for the animal community and leaves, flowers, and fruits are consumed mainly by insects, birds, bats, and small mammals. Chemical defenses are common among tropical forest plants and many species have developed mechanical defenses by incorporating silica, lignin, and fibers in their tissues.

Tropical Semideciduous and Dry Forests

Along the gradients from tropical rain forest to dry forest, the structural and functional attributes of the ecosystems change. Tropical deciduous forests correlate with climates of two well-determined seasons: a rainy period followed by a dry one. More than 50% of the tree species shed their foliage during the dry period. The predominant characteristic of the habitat of these forests is the prolonged seasonal drought, causing desiccation of the topsoil and lowering atmospheric humidity. The length of the dry season determines the degree of divergence in physiognomy and structure of the seasonal forest (Gentry, 1995). From wet evergreen to dry deciduous forests, prolonged drought correlates with a reduction in

physiognomy and floristic composition and the lowering of canopy height. At the same time, the degree of deciduousness of the trees of the overstory increases. The phenology of these ecosystems is determined by a seasonal climate with a period of intense summer rainfalls followed by a dry winter. In the southern dry deciduous forests, the winter season also brings changes in mean temperature down to 15 °C. Although between 20% and 50% of the woody species found in these ecosystems are deciduous, these forests are still dominated by Amazonian genera widely distributed across South America, such as *Parapiptadenia*, *Peltophorum*, *Cariniana*, *Lecythis*, *Tabebaia*, *Astronium*, and others of lesser physiognomic importance (Murphy and Lugo, 1986).

Although tropical rain forests contain the highest diversity of species measured in terrestrial ecosystems, life-form diversity is higher in dry forest probably because of habitat heterogeneity. Woody plants in tropical rain forest tend to converge to a small number of lifeforms. In drier seasonal environments, the proportion of deciduous trees and shrubs increases, the presence of epiphytes decreases, and vines become more frequent. The presence of epiphytes is associated with high air humidity and the presence of dew (Gentry, 1995). Along seasonality, gradients succulent plants conspicuously increase, including those with Crassulacean acid metabolism (CAM). Succulent-stemmed plants have very stable water relations and are drought resistant. Evergreen woody plants dominate at both extremes of the gradient, and although they all belong to the C3 photosynthesis type, there are differences in their leaf structure and drought resistance, which allow them to function in both mesic and arid environments (Murphy and Lugo, 1986).

Savannas, Grasslands, and Shrub Lands

Distribution and Structure

Savannas and grasslands occupy nearly 25% of South America in both tropical and subtropical regions.

Tropical Savannas

These ecosystems are characteristic of the warm lowland tropics and occur in areas with a strongly seasonal rainfall regime and a dry period lasting from 4 to 7 or 8 months. Although a herbaceous cover consisting mostly of bunch grasses and sedges is dominant in savannas, the term "savanna" embraces a variety of vegetation types found in tropical latitudes. An important characteristic of tropical savannas is a clear seasonality in their phenology and a period of lower activity associated with times of water stress. According to Sarmiento (1984), tropical savannas can be divided into four functionally distinct types: (1) semiseasonal savannas, with weak water stress conditions; (2) seasonal savannas, with a distinct rainfall seasonality and common fires during the dry season; (3) hyperseasonal savannas, where in addition to a marked dry season there is also a period of water flooding; and (4) "esteros," which are areas without a clear dry season, but an excess of soil water for most of the year.

The largest extension of savanna in South America occupies the old Precambrian Brazilian shield and has been dubbed by phytogeographers "Cerrados." Savanna ecosystems are also

found in the Orinoco Llanos of Colombia and Venezuela, in Suriname, Guyana, in some Amazonian regions of Brazil, and in Paraguay, Bolivia, Argentina, and the northern Chaco region (Figure 3). The vegetation of the Guyanan savannas is more related floristically to the llanos than the cerrado.

Perennial grasses, herbs, and shrubs are the dominant life forms in savanna ecosystems. They are well adapted to the seasonal climate, soils poor in nutrients, and the fire disturbance regime that dominate in these environments. At least five phenological groups of grasses have been recognized in savanna ecosystems: perennial with a seasonal semidormant period, annual ephemeral with a short cycle, annual with long cycle, perennial with a seasonal dormant period, and of continuous flowering and growth (Coupland, 1992). Tree species found in savannas have adapted to these conditions by increased allocation to underground biomass. Trees in woody savannas can reach 25–30 m in height, but their diameter rarely exceeds 50 cm. Some savanna tree species are described as subterranean trees because their roots can penetrate to depths of 18 m. Other species like *Curatella americana* have shallow roots that can grow more than 20 m horizontally and secondary roots that can reach depths of 6 m. Other conspicuous components of savanna landscapes are the gallery forest along rivers and smaller streams and the seasonally inundated palm communities (*morichales*) dominated by the palm *Mauritia flexuosa*.

In the Brazilian Cerrado, there is a series of plant communities from open grasslands to dense woodlands and more or less recognizable stages in this continuum receive vernacular names. Dry grasslands without shrubs or trees are called "campo limpo" (i.e., clean field); grasslands with scattered shrubs are called "campo sujo" (i.e., dirty field); grasslands with numerous trees and shrubs are called "campo cerrado" (i.e., closed field); when the vegetation is dominated by a closed canopy of trees it is called "cerradao" (i.e., the vegetation is closed). The latter is a woodland composed of trees often 8–12 m or even taller, with ground vegetation reduced because of the shade. Many factors probably determine which of these forms of Cerrado vegetation occurs in a given locality, among them topography and soil texture seem to have the main causal effect. Cerrados have a markedly seasonal climate and possess a large characteristic flora of fire-resistant plants, including about 800 species of trees and large shrubs, and many times that number of herbs and subshrubs. The vast majority of these species are endemic to the Cerrado, an ancient vegetation formation dating back perhaps 50 million years (Coupland, 1992).

Temperate Grasslands

These ecosystems occupy the eastern part of southern South America in Argentina, Uruguay, Chile, and southern Brazil. They expand across the pampas of Rio de la Plata in Argentina, the Chaco region, the semiarid region west of the humid pampa (*Monte*), and reach the edges of desert and semidesert areas of the Patagonian region (Figure 3). The dominant landforms are large plains with a few table-shaped outcroppings no more than 500 m above the plains. The dominant climate across the large grassland region is characterized by a mean temperature of 10–20 °C with an annual precipitation ranging from 400 to 1600 mm. The dominant soil types

are young and include Mollisols, Alfisols, Vertisols, and Entisols.

Vegetation in the Pampean temperate grasslands is composed of about 1000 species and varies from grass-dominated communities in the east, to xeric woodlands and semidesert communities in the west. In the Argentinean Pampas, plant communities are dominated by species of *Agrostis*, *Bouteloa*, *Elyonurus*, *Festuca*, *Panicum*, *Paspalum*, and *Stipa*. In Chile and northward in the Andes, the ecosystems of grasslands are dominated by species of *Andropogon*, *Bromus*, *Calamagrostis*, *Poa*, *Sporobolus*, *Eragrostis*, and *Distichlis*. It is difficult to determine the proportion of Patagonia that can be classified as grasslands, because the sparse vegetation is mostly dwarf shrubs and grasses do not form a continuous cover, therefore many areas are treated rather as deserts.

High Andean Grasslands

These ecosystems are found above the tree line (3000–4500 m) of the Andean range in Colombia, Venezuela, Ecuador (*Paramo*), Peru, Bolivia, and Chile (*Puna*). The actual lower limit of paramo and puna ecosystems depends on exposure, the climatic regime, and in particular precipitation. The dominant life-forms of the Andean grasslands are giant-rosette plants (known locally as "*frailejon*"), tussocks of grasses or sedges, acaulescent rosette plants, cushion plants, cacti, and sclerophyllous shrubs. The giant-rosette plants can reach heights of several meters and have developed a number of morphological and anatomical adaptations including the retention of dead leaves that cover the shoot and provide insulation. At higher elevations, the vegetation cover becomes sparser and shrubs and herbs replace bunch grasses.

Functional Aspects

Tropical Savannas

Relatively homogeneous temperature and a well-defined wet season characterize the Tropical Savanna (*Aw*) tropical savanna climate or dry-wet tropical climate (Figure 2). The alternation of wet and dry periods coincides with the presence of tropical savanna vegetation, characterized by open spaces covered by grasses and spaced trees. Soils are mainly latosols of low fertility, formed by similar processes but not as deep as those found in the *Af* climate.

Savanna ecosystems are characterized by seasonal growth cycles that follow the annual precipitation cycles. However, the phenology patterns of savanna plants are very asynchronous resulting in different patterns of productivity, reproduction, and decomposition. Most grasses usually start growing at the beginning of the rainy season and reach reproductive stages early in the wet season or a few months later. Some vegetative growth continues throughout the year but at the end of the dry season, all aboveground biomass is dead. In perennial grasses, all the aboveground biomass dies by the end of the dry season and in the following year is replaced by vegetative growth of subterranean perennial organs. In evergreen species, growth of leaf and shoot biomass and reproduction generally occur during the dry season. Leaf development stops at the beginning of the wet season, and before the dry season begins, leaves are shaded. In most evergreen species, however, growth of stems and other woody parts only occurs during the wet season.

Usually there are layers of laterites under savanna soils that originated during the Cretaceous and Tertiary periods. Continuous weathering has produced soils poor in nutrients and with high acidity and concentration of aluminum that immobilizes phosphorous as iron–aluminum phosphate. In the soil environment, marked annual differences occur particularly in the upper soil layers where moisture levels can exceed field capacity during the wet season and diminish to wilting point during the dry period.

The stock of nutrients in savannas varies over the year as they move from different compartments of the ecosystem. The largest fraction of nutrients is stored in the aboveground biomass. Savanna trees tend to accumulate fewer nutrients than similar dry forest species and some nutrients reallocate from leaves to other organs before shedding occurs. Some nutrients accumulated in grasses return to the soil after fires but large fractions of nitrogen, phosphorous, and potassium are lost to the atmosphere when biomass burns. Decomposition of leaf litter by microorganisms occurs during the wet season and termites consume most of the woody material during the dry period.

The flora of the Brazilian cerrado and other South American savannas has typical features of pyrophytic vegetation. Trees are low, of contorted form, with thick, corky, fire-resistant barks; sclerophylly is common, and many leaves have thick cuticles, silicified tissues, and are often of considerable longevity. The underground organs of perennial grass species are protected from fire and their seeds as well as those of annual species are adapted to fire; in fact, the germination of many grass species is stimulated by fire events (Eiten, 1972). Because savanna vegetation is adapted to resist burning, occasional natural fires must have been an environmental factor throughout its history. Frequent burning favors the herbaceous, as opposed to the woody, component of the vegetation and when this occurs, savanna woodlands are transformed into grasslands. Conversely, protection from fire often has the opposite effect and a type of dense savanna woodland with considerable shade and only a very sparse grass layer is established. Some authors have correlated increasing production of woody vegetation with an increasing soil fertility gradient. Soil moisture is another factor that controls many of the most obvious differences in vegetation in the savanna landscape (Eiten, 1972). In general, woody vegetation occurs only on soils well drained throughout the year. Swampy gallery forest is found where the water table is permanently high.

Temperate Grasslands

There are different hypotheses that attempt to explain the physiognomic origin of the temperate grasslands. An initial hypothesis proposed that pre-Columbian people burned an original scrub forest. Another hypothesis points to an adaptive dominance of grasses due to a climatic effect that maintains a negative water balance during part of the year. Although there are significant regional differences, edaphic factors such as the fine texture of soils are proposed as major causes for the dominance of grasses. A lack of air spaces in the soil combined with summer dry periods would favor the competitive ability of grasses over trees. A variety of root growth habits is observed among both grasses and shrubs and the stratification of root

biomass along the soil profile minimizes competition for water and nutrients. The dominant species of grasses are perennial, live for 3–4 years, and are short and leafy.

The soils of the southern grasslands usually present bad drainage conditions, relatively acidic pH, and the humus layer can be 30–40 cm deep. Deeper soil layers are less organic, more alkaline, and composed mostly of clay or calcareous sediments. From west to east, soil depth and organic matter content decrease because in drier areas productivity is lower. Soils are relatively poor in nitrogen and phosphorous, which frequently limit grassland productivity. Nitrogen accumulates mainly in organic forms; it is quickly absorbed and stored in leaves and live root biomass. Fungi are the most important decomposers in grassland ecosystems, and nematodes are the principal soil invertebrates. In the flooded Pampean grasslands, phenological studies have shown that there is not a well-defined growing season. These grasslands are subject to periodic flooding and drought almost every year and floristically different plant communities occur according to various degrees of perturbation (Coupland, 1992).

South American grasslands have been greatly modified by humans through burning, grazing livestock, and agriculture. Before these intensive activities took place, there were a vast number of ungulates like the Guanaco (*Lama guanicoe*) and the Pampas deer (*Ozotoceros bezoarticus*). Birds are still abundant with more than 390 species described, of which the most conspicuous is the Nandú (*Rhea americana*). Reptiles and amphibians are also abundant with poisonous snakes (e.g., *Bohtrops alternata*), caimans (e.g., *Caiman latirostris*), lizards (e.g., *Teius teyou*), toads (e.g., *Bufo refus*), and frogs (e.g., *Hyla pulchella*).

High Andean Grasslands

The most important functional attributes of these ecosystems are associated with the extraordinary amplitude of daily fluctuations in temperature and humidity, which are more pronounced than the seasonal ones. In these environments, high daytime temperatures follow nocturnal frost causing significant physiological stress in both plants and animals. Plants have evolved mechanisms that allow them to grow during the whole year. The frailejon giant-rosettes, for instance, at night protect their buds in the center of the rosette by adjusting the position of their leaves. In addition, these plants have large intercellular air spaces and excrete mucilage that contributes to their heat-storage capacity. The discontinuous areas of paramo ecosystems are isolated by montane wet (cloud) forests that grow at lower altitudes and as a result there is a large number of endemic species. Nutrient dynamics in high Andean ecosystems are not fully documented. In general, low temperatures and moist acid soils slow decomposition rates, and a thick layer of organic humus usually accumulates in sites where the relief allows deposition.

Xeric Formations

In South America there is a variety of xerophytic ecosystems, all marked by an intensive and prolonged period of seasonal drought during which the vegetation suffers water deficit.

Distribution and Structure

A mean annual precipitation of 400–1200 mm and more extreme daily changes of temperature characterize the Dry Climate Steppe (BS) climate. Soils are brown and yellowish, reflecting a higher content of humus. The BS climate coincides with the geographic distribution of semiarid environments and generally represents transitions between desert environments of the type Dry Climate Desert (BW) and savanna environments of the type Aw (Figures 2 and 3). In South America, xeric ecosystems are represented by the xeric scrubs of La Guajira peninsula in Colombia and Venezuela, the Paraguaná xeric scrub of Venezuela, the dry forest of west Ecuador, the Sechura and Atacama deserts in Chile, the Gran Chaco region in southern Bolivia, west Paraguay and north Argentina, and the Caatinga xeric scrub of northeastern Brazil (Figure 3). The dry highland plateaus of the Puna region and the thorn woodlands of Patagonia are usually included within the dry formations of the continent. There is also a xeric formation called "agreste," which forms a narrow strip between the Caatinga and the seasonal forest of eastern Brazil. Although not a strictly xeric ecosystem, the Matorral of Chile is also usually included as a semiarid type of vegetation (Figure 3).

Deciduous forest trees that severely restrict their transpiration during the middle of the day – even during the rainy period – characterize the thorny woodlands of Colombia, Venezuela, and northeastern Brazil. Significant areas of the Guajira region consist of sand, moving dunes. Only a few trees are evergreen, but along the periodically dry channels of streams, riparian vegetation retain their leaves and reflect the presence of groundwater. The mean canopy height of the woody components is 5 m, sometimes reaching 7 m. The most important genera in these plant communities are *Acacia*, *Bulnesia*, *Bursera*, *Caesalpina*, *Capparis*, *Croton*, *Jacquina*, *Opuntia*, and *Prosopis*. The caatinga ecosystems in the larger "Sertao" depression of northeastern Brazil are dominated by the genera *Canavillea*, *Chorisia*, and *Schinopsis*. Communities on the dry tablelands are dominated by the genera *Spondias*, *Commiphora*, *Cnidocolus*, *Aspidosperma*, and *Mimosa*. The driest parts of the Sertao are dominated by the genera *Mimosa*, *Auxema*, *Combretum*, and *Aristida*. The Agreste formation between the Caatinga and seasonal forest of Brazil has an open canopy of xerophytic trees (mostly Leguminosae and Myrtaceae) with a very scanty understory of palms (e.g., *Copernicia cerifera*) and cactus.

The ecosystems of the Gran Chaco region are structurally diverse, reflecting the varied environmental changes observed across the Chaco range. Precipitation increases from the center of the region, both to the east and west. The landforms are flat in the west and north and during the rainy season, flooding is common. The thorn woodlands of Patagonia occupy the west margin of the Pampa region, where annual precipitation is lower (300–500 mm) and the woody components of the vegetation (Acacias and palms) are characteristically undersized.

Owing to the effect of the Andes and climatic circulation patterns (see Climate), an arid zone occupies the zone from the coasts of Peru and Chile across the mountains into the Patagonian steppes (Figure 3). The Pacific coastal area is a desolated desert where rain can be absent for years. The

Atacama Desert is the driest climatic region of South America and occupies the eastern Pacific coast of the continent from about 5° to 26° S (Figures 2 and 3). In many areas there is no fog to provide moisture for vegetation and the cover is dominated by lichens and algae that depend on water condensed as dew. In those areas where fog and clouds develop, bringing a few millimeters of annual precipitation, there are some short-cycled annual plants from the genera *Aristida*, *Loasa*, *Malesherbia*, *Nolana*, and *Tropelium*. On the west-facing slopes, between 100 and 150 m, moisture from fog carried by the Humboldt Current allows the presence of some vegetation. Some of the common species in these ecosystems are *Prosopis juliflora*, *Distichilis spicata*, *Capparis angulata*, *Sporobolus virginicus*, *Acacia macracantha*, and the giant cactus *Neoraimondia gigantea*. In the high Andean slopes, the lowland forests and the grassland Puna limit the dry ecosystems of the Andean Peruvian valleys. In the dominant genera there are *Acacia*, *Bombax*, *Bursera*, *Caesalpinia*, *Cercidicum*, *Prosopis*, *Puya*, and several cacti.

The Mediterranean Matorral occupies the coastal west-facing slopes of the Andes in central Chile (Figure 3). Plant communities in these ecosystems are composed of evergreen shrub species that reach 3–5 m in height and have characteristic sclerophyllous leaves (e.g., *Lithaea caustica* and *Fluorencia thurifera*), while succulents and herbs cover the ground. Some Acacias and *Nothofagus* are present in communities of higher areas and those found further inland. Despite its latitudinal position, the flora of the Chilean Matorral is very rich, with more than 2000 species reported.

Functional Aspects

There are only a few studies on the physiology and phenology of South American xeric ecosystems. Most of these ecosystems are characterized by at most 3–5 months of rainy season with not more than 400–800 mm per year. In tropical lowland areas, temperatures are 23–27 °C year round. Relative humidity is stable around 50% and the potential evapotranspiration is usually 1500–2000 mm per year. Plant communities are affected by water deficit, which varies greatly from region to region, and so do the physiognomic and physiologic responses of the vegetation. Some annual plants germinate, grow, and reproduce only during periods of available water (e.g., most herbaceous). Other plants evade stress conditions by restricting growth to periods of available water, while the shedding of leaves is a common adaptation to cope with the long dry periods. Since leaves are only present during the rainy season, many species have not developed mechanisms to control evapotranspiration. In addition, many species from these ecosystems produce leaves with chemicals that inhibit the germination of other plants. CAM is common and succulent perennials use this type of photosynthesis to endure the scarcity of water.

Annual precipitation of about 300–900 mm and a dry summer climate characterize Mediterranean ecosystems. The dry, hot weather favors the occurrence of fires, which is the main disturbance in these ecosystems. Topographical conditions are also important in Mediterranean ecosystems, where erosion and continuous rearrangement of surface materials are common. In Chile, the duration and intensity of the drought period increases southward and Matorral

communities become dominated by deciduous evergreen shrubs and succulent species. The climatic conditions allow all shrub species to use C3 photosynthesis to fix carbon and there are not species with C4 metabolism. As already pointed out, the availability of soil resources is important in determining the investment that plants make on belowground biomass. In the Chilean Matorral it has been estimated that shrubs have an average root to shoot ratio of 1.5 and the roots spread in a radius at least two times the area of their crowns. Most of the fine absorbing roots, however, are found under the crown where they absorb nutrients from decomposing leaves and debris. Water availability appears to be the most important controlling factor of productivity in Matorral ecosystems. Annual productivity in these ecosystems range from 2 to 6.5 kg m⁻².

Coastal Ecosystems and Wetlands

Mangroves

In South America, mangroves occur along fragments of the Atlantic coastlines of Colombia, Venezuela, Guyana, Surinam, French Guyana, and Brazil, and the Pacific coastlines of Colombia, Ecuador, and Peru (Figure 3). Mangroves develop well in areas where the ocean temperature remains above 24–27 °C. Because of the effect of ocean currents (see Climate), the southern limits of mangroves in South America occur at about 25° S in the Atlantic coast of Brazil and 4° S in the Pacific coasts of Ecuador and Peru.

These woody communities can grow up to 30 m. The mangle is best developed in coastal areas where high rates of sedimentation are enhanced by the mangroves themselves. Local topography, runoff channels, and sediment stability determine distinct zonal patterns. The vegetation of mangrove ecosystems (mangal) is adapted to salinity and is dominated by *Rhizophora mangle*, *Avicenia* sp. and in high ground by *Laguncularia racemosa*. Plant communities directly influenced by seawater but occupying high grounds are characterized by genera typical of seashore environments: *Remirea*, *Salicornia*, *Canavalia*, *Acicarpa*, and *Vignia*.

Mangrove areas are sometimes associated with river deltas and coastal swamps that have habitats in which the soils are inundated for at least part of the year. In the mouth of the Amazon, however, mangroves do not grow well. According to the quality of the water, it is possible to distinguish freshwater swamps and brackish water swamps. To the first type belong the freshwater swamp forests of the Atlantic coast between the Orinoco delta and the mouth of the Parnaíba River. Most of the other mangrove swamp forests belong to the second type. Other conspicuous coastal ecosystems are the Restingas of the Brazilian coast. These ecosystems are characterized by sand dunes where low scrubby vegetation grows sparsely. Their flora is rich in endemic species.

Wetlands

In South America, there are many dispersed wetland ecosystems. Some savanna areas of the Llanos region in the Orinoco watershed and the Rio Branco in Brazil have bad drainage and are seasonally inundated. In Ecuador, west of the Daule River, there is also a region of wetlands. The complex of

grassland and woodland savanna vegetation occupies flat plains with tropical seasonal climate. The different types of vegetation are closely associated with the duration of the period of inundation. Areas with a long inundation period maintain communities dominated by the genera *Euterpe* and *Mauritia*. The genera *Typha*, *Cyperus*, and *Juncus* dominate swampy areas. In well-drained floodplains, the dominant genera are *Panicum*, *Paspalum*, and *Thalia*.

In western and eastern Amazonia there are also some areas of flooded grasslands but larger wetland ecosystems usually occupy the floodplain of large rivers (e.g., varzea and igapo in Amazonia) and the structure of the plant communities depends on the level and duration of the flooding period (see Tropical Forest: Functional Aspects). The larger wetlands of the continent are in the Gran Pantanal region in Brazil, Bolivia and Paraguay, and the Paraná flooded savannas in Argentina (Figure 3). The Pantanal occupies the upper watershed of the Paraguay basin and is one of the world's largest wetlands, which is flooded in more than 80% of its area during the rainy season (from May to December). The geomorphology is essentially flat and small high-ground islands separate hundreds of small lagoons. Cerrado tree species and palms occupy the high-ground islands of the Pantanal. The region accommodates large seasonal migrations of wildlife including aquatic birds and caimans.

Temperate Forests

In South America, temperate forests have a limited distribution and are restricted to relatively small areas. These ecosystems occur in the southern Andean areas of Chile and Argentina (Figure 3). Evergreen temperate forest occupies areas of frost-free oceanic climate. These ecosystems are dominated by tall trees, some reaching heights up to 50 m, and composed of species such as *Eucryphia cordifolia* and *Laurelia philippiana* and some conifers like *Araucaria araucana*.

In the western humid slopes of the Andes, temperate rain forests are divided into the Valdivian and Magellanic forests. The Valdivian rain forest has an upper limit of 500 m and occurs from 40° S to 47–49° S where it becomes the Magellanic forest. Lush vegetation rich in evergreen species, abundant epiphytes, and lianas characterizes Valdivian ecosystems. The Valdivian forests can support an extraordinary biomass, in part because the climate is very humid and the mean annual temperature ranges from 10 to 12 °C. In areas with excessive humidity, coniferous trees (*Fitzroya patagonica*) – whose stands can reach heights of 50–60 m – replace common species of the rain forests. Coniferous forests also grow well at higher altitudes up to the tree line, which in the southern cone occur at about 1600–1900 m above sea level. Between the Valdivian forests and the sclerophyllous vegetation of central Chile there are limited extensions of deciduous forests composed of *Nothofagus obliqua*, which are found up to 1200 m above sea level.

The Magellanic forests occupy the western slopes of the Cordillera Patagonica in southern Chile. In this region, the coastline is very rocky, curved by fjords, and has an abrupt slope. Abundant rainfall, low evapotranspiration, and strong

winds characterize the climate. The Magellanic forests are poor in species. As precipitation decreases rapidly to the east, in the leeward slopes, deciduous forests occur and are composed almost of pure stands of *Nothofagus* with an understory of small evergreen trees. These forests grow to heights of about 30 m, but they become shorter as altitude increases. The tree line falls from 1200 to 1400 m in the north to about 600 m in the region of Ushuaia.

Glossary

Biological diversity (biodiversity) The collection of genomes, species, and ecosystems occurring in a geographically defined region (NRC, 1995).

Coastal zone Zone whose terrestrial boundary is defined by (a) the inland extent of astronomical tidal influence or (b) the inland limit of penetration of marine aerosols within the atmospheric boundary layer and including both salts and suspended liquids, whichever is greater; the seaward limit is defined by (a) the outer extent of the continental shelf (approximately 200 m depth) or (b) the limits of territorial waters, whichever is greater (Hayden *et al.*, 1984).

Estuary Semienclosed coastal body of water that has a free connection with the open sea and within which seawater is

measurably diluted with freshwater derived from land drainage (Pritchard, 1967).

Functional diversity Variety of different responses to environmental change, especially the diverse time and space scales with which organisms react to each other and to the environment (Steele, 1991).

Metapopulation An abstraction of the population to a higher level at which individuals frequently move from one place (population) to another, typically across habitat types that are not suitable for their feeding and breeding activities, and often with substantial risk of failing to locate another suitable habitat patch in which to settle (Hanski and Gilpin, 1991).

Introduction

Some of the steepest environmental gradients on planet Earth occur in the coastal zone, where land, sea, and atmosphere uniquely interact and exchange energy and materials. The dynamic linkages among biological, physical, and chemical systems are exceptionally strong in estuaries, characterized by cyclic changes that occur at different frequencies – such as for tides, salinity cycles, freshwater inputs, light, and temperature stratification. Estuaries also bear the brunt of extreme events, such as flooding, storms, hurricanes, and impacts of seasonal sea ice. All of these features are important for organisms, which have evolved suites of adaptive mechanisms to cope.

Estuaries have usually been considered as transitional areas between fresh and saltwater environments. However, relatively few species are totally confined to estuarine conditions, even though various stages of many species' life cycles are estuary-dependent. This raises questions about whether estuaries can be considered as transitional or as more-or-less autonomous ecosystems. The distribution of biodiversity provides important information toward the resolution of this apparent dichotomy, which needless to say is essential with respect to conservation and management.

Our present knowledge about estuary-dependent biodiversity is sparse. Fundamental questions remain about species distributions in estuaries, in what ways species are adapted to estuaries, and how some species may affect others by means of structural or functional interrelationships. Furthermore, the diversity of estuaries relative to other ecosystems remains to be clarified. These questions require both ultimate, historical-evolutionary explanations and proximate, functional-ecological considerations.

Estuaries are located in the critical portion of Earth called the "coastal zone," which accounts for a disproportionate amount of global ecological functions. For example, the coastal zone (modified from Pernetta and Milliman, 1995; see also Crossland *et al.*, 2005):

- occupies only 18% of the surface of the globe, 8% of the ocean surface, and 0.5% of ocean volume;
- but provides for up to 50% of global denitrification, 80% of global organic matter burial, 90% of global sedimentary mineralization, 75–90% of the global sink of suspended river load and its associated elements/pollutants, and more than 50% of present-day global carbonate deposition;
- also supplies approximately a quarter of global primary production, around 14% of global ocean production and 90% of the world fish catch.

Despite this coastal zone association, the *Global Biodiversity Assessment* (Heywood and Watson, 1995) contained no sections specifically devoted to estuaries, but did characterize biodiversity as comprising three disciplines, which also apply to estuaries: (1) taxonomy: provides the reference system and depicts the pattern or tree of diversity for all organisms; (2) genetics: gives a direct knowledge of the genetic variations found within and between species; and (3) ecology: provides knowledge of the varied ecological systems in which taxonomic and genetic diversity are located, and also provides information on functional components. Evolutionary biology brings these fields together, as it "provides explanations of how biodiversity arose, and the processes, such as speciation and extinction, by which it continues to change." Nevertheless, a comprehensive understanding of the functional biodiversity

of estuaries remains a future goal, and is the focus of this article. In this respect, it is worthwhile to note that, even today, estuarine science continues to be organized along disciplinary lines. Although the study of land-seascape ecology of estuaries remains in its infancy, there are extensive publications on geomorphology, land-sea interactions, coastal zone management, and other disciplines from which to gain an integrated understanding of estuaries, but which are beyond the scope of this review.

Ironically, estuaries became topics of intensive concern and research only in the mid-twentieth century, whereas humans have lived in close proximity to estuaries and have been dependent on them and their biological resources for millennia. Reasons for human proximity to and dependence on estuarine environments are both social and ecological, for estuaries are ecologically diverse and productive, making possible the sustainment of large and sophisticated human societies. Indeed, it is more than coincidental that among the first known city-states were those of the lower reaches of the Tigris and Euphrates Rivers of Mesopotamia.

The distribution of estuaries corresponds to regional and coastal characteristics; that is, they tend to be extensive, large, and numerous where coastal plains are wide and flat, but are relatively small where coastal plains are steep and narrow. Particularly in the former, estuaries and associated lagoons constitute a much higher percentage of the coasts than is generally recognized. In fact, many of the world's largest cities (London, New York, Karachi, Amsterdam, Alexandria, Tokyo, etc.) have been built on or near drained marshes or filled land adjacent to estuaries. In the USA 80–90% of the Atlantic and Gulf Coasts and 10–20% of the Pacific Coast consist of estuaries and lagoons (Emery, 1967).

As noted above, estuaries are best understood in the context of the coastal zone, definitions of which vary. Ketchum (1972) was among the first to take a functional perspective, that the coastal zone "is the broad interface between land and water where production, consumption, and exchange processes occur at high rates of intensity." NERC (1992), however, defined the coastal zone as: "An indefinite zone of land and sea that straddles the shoreline; includes all land that is the product of, and/or at risk from (Holocene) marine processes, and extends seaward from the shoreline to water depths of about 30 m." The key element is "marine processes" and, from that point of view, it seems best to adopt Ketchum's broader view. Accordingly, Hayden *et al.* (1984) adopted Ketchum's definition (*see* Glossary), which makes sense of such interactions as the existence of coastal vegetation under the influence of aerosols, sedimentation induced by freshwater flows and atmosphere-ocean processes, and the coastal distribution of aquatic biota worldwide. With respect to the latter, Nelson (1984) estimated that of about 21,700 described species of fishes, about 8400 (39%) occur in freshwater and 2700 (12%) are oceanic. Nearly half of these fishes (10,200 species, or 47%) are coastal, that is, occur from estuaries to the outer extent of the continental shelf. This proliferation of fish diversity is powerful evidence of the functional importance and the extent of the coastal zone. (Later editions of Nelson (1984), in 1994 and 2006, predict that the total species of fish might reach more than 28,000 and 32,000 species, respectively – greater than the combined

total of all tetrapods – but the proportions originally given remain approximately the same.)

Within this coastal zone context, Pritchard's (1967) definition of "estuary" is most generally accepted (*see* Glossary). Additionally, Pritchard's definition takes account of Pleistocene rises and falls in sea level, as well as of terrestrial processes, such as sedimentation, which clearly affect distributions of biota. However, other definitions include that of Mann (1982), who defined an estuary as "a region where river water mixes with, and measurably dilutes, sea-water." However, this definition could include semienclosed seas (e.g., the Baltic), plumes of large rivers, and diluted water off open coasts, making difficult any geographic analysis of estuarine biodiversity or function.

In this coastal zone context, estuaries are subject to rapid environmental, structural-functional change, which has major consequences for biodiversity. Hydrological, biological, and sedimentary processes and events may substantially alter or destroy estuaries. Thus, the estuaries that we now see are the result of the latest major episodes of sea level fall and rise; in fact, the age of the present estuaries is only about 1% of the age of the continental shelf (Emery, 1967). It is reasonable to assume that the communities of estuarine biota that exist today are as young and equally subject to change, most notably as a result of human activities.

Many estuaries around the world have been studied in some detail. The North American bias in this article reflects the considerable body of research that has been conducted on North American estuaries during the past few decades, motivated unfortunately by the depleted, overenriched, polluted, and overpopulated states of many of them, some aspects of which will be examined in A Case Study: The Chesapeake Bay, below.

Estuarine Classification

Classification is essential as a reference system among estuaries. Various physical classifications, or typologies, of estuaries facilitate comparisons, but no typology has yet been directed specifically to estuarine biodiversity. To our knowledge, the first classification was the so-called "Venice system" ("V" – Anonymous, 1959), in which estuaries were divided into salinity zones. This system was later modified by on the basis of species' salinity tolerances ("B" – Bulger *et al.*, 1993). These two schemes align rather closely and may be compared as follows (ppt=parts per thousand): Limnetic (freshwater), 0.5 ppt (V), 4 ppt (B); oligohaline 0.5–5 ppt (V), 2–14 ppt (B); mesohaline 5–18 ppt (V), 11–18 ppt (B); polyhaline 18–30 ppt (V), 16–27 ppt (B); euhaline 30 ppt–full marine (V); 24–ppt marine (B).

The reason for the differences in salinity ranges between these two systems is that the former was derived from salinity, whereas the latter was derived analytically from species' salinity tolerances. In both cases, however, the compartments are oversimplistic, as estuaries exhibit many characteristics that influence biotic distribution and the distinction of estuarine zones, variably identified as "upper reaches," "upper-middle reaches," "lower reaches," and so forth. Nor do salinity-derived systems distinguish zones according to variations in bottom

type, water movement, volume of flow, and other attributes important to the biota.

Another classification concerns basin geomorphology, which is of obvious importance with respect to circulation patterns. Classification on this basis appears in many texts and may be summarized as:

- Coastal plain estuary (drowned river valley): Usually confined to areas with a wide coastal plain where seawater has invaded existing rivers because of sea level rise since the Pleistocene. Generally the up-estuary limit is where chlorinity is about 0.06‰ (salinity about 0.1‰); above this point there may be a portion of tidal freshwater.
- Fjord: Generally U-shaped in cross section due to glacial scouring, in which the sides are steep. May be fed by a river, have a deep basin, and a shallow sill may be present near the mouth.
- Bar-built: Occurs in flat, low-lying areas, where sand tends to be deposited in bars lying parallel to the coast. Usually shallow and wind-mixed. Can be a composite of drowned river valleys and embayments, and occurs where offshore sand barriers are built between headlands into a chain enclosing a body of water. May be fed by multiple rivers, but the total drainage area is usually not large.
- Tectonic: A miscellaneous category including estuaries formed from faults or folding of Earth's crust. Often have an excess of freshwater flow.

The interchange of freshwater and seawater provides yet another classification. The inlet (mouth) must be of sufficient dimension to allow mixing of seawater and freshwater, and the dilution of seawater provides the density gradients that drive characteristic circulation patterns. In terms of this interchange, the general classification is:

- Salt wedge: wherein a layer of relatively freshwater flows out at the surface.
- Partially mixed (moderately stratified): wherein tidal flow, turbulence, and mixing are increased, tending to erase the salt wedge.
- Vertically homogeneous: wherein tidal flow is strong, river runoff is weak, and all stratification is broken down.

Combinations of these typologies are possible; that is, it may be possible to find a stratified or a mixed bar-built estuary, or a fjord with a salt wedge or not. Furthermore, the extents of salinity zones can vary considerably for all categories. Such combinations of structure and hydrologic process result in highly varied conditions in the distributions of sediment, phytoplankton, submerged aquatic vegetation, and fishes and invertebrates. Additionally, variations in freshwater inputs, circulation, turbulence, and mixing can modify the typology.

A final classification concerns estuarine evolution. Roy (1984) described estuaries of three successional types for estuaries of New South Wales, Australia: drowned river valleys, barrier estuaries, and saline coastal lakes. Infilling during relatively short time spans affected their size, configuration, the invasion of mangroves and other aquatic vegetation, and fish communities. Faunal population densities and species diversity increase with ecological complexity,

but as infilling becomes more advanced the estuary becomes simplified and biological diversity declines. Therefore, estuarine geology, hydrology, and biology form a hierarchical succession and biodiversity maxima are reached in intermediate stages.

Estuarine Biodiversity

From the foregoing discussion, the impression may be gained that estuaries are simply transitional and, therefore, not biologically diverse. Indeed, Sanders (1968) found that estuaries are relatively nondiverse biologically, while noting: "What is significant is that each environment seems to have its own characteristic rate of species increment." This is to say that although salinity, for example, is an important determinant of the distribution of biota, estuaries exhibit high and dynamic habitat and land-seascape diversity, a consequence of which is high variability among the biota and a high degree of biotic interaction. Thus, estuarine biotic communities would be expected to be especially complex, contrary to earlier impressions of estuarine biological and ecological simplicity. Additionally, their biota have evolved resiliency to natural disturbance. This is expressed at species, community, and ecosystem levels, leading to the simplistic impression that estuarine species are facultative with respect to estuaries as preferred environments. These characteristics have resulted in a tendency to describe any species that enters estuaries, or those that tolerate brackish waters, as "estuarine," a characterization that can be misleading. However, many estuarine fishes and invertebrates move in or out of estuaries and appear to be transients. Conversely, some species seem to be restricted to estuarine and near-shore environments, at least at some life-history stage. A notable example concerns temperate oysters (*see* A Case Study: Chesapeake Bay, below) that build extensive reefs in estuaries and lagoons and nowhere else, providing habitat for dozens of species, representative of almost every animal phylum. Therefore, it has been challenging to define an "estuary-dependent" organism.

Carriker (1967) noted that estuarine biota have adapted in different ways to estuarine conditions; for example, oligohaline organisms disappear below the head of the estuary; euryhaline species constitute the majority of the estuarine biota, as they can tolerate salinities as low as 5 ppt, as well as full salt water; and stenohaline species do not tolerate salinities of <25 ppt and are found only at the mouths of estuaries or on open seashores. This leaves "true estuarine organisms" – those relatively few species that are restricted to estuaries and that are best represented in the upper and middle reaches. Carriker concentrated mainly on benthic invertebrates, but concluded that an "estuarine biocenose" may be justified as a discrete functional aggregation of interdependent, regularly recurring, dominant, benthic populations that are strongly represented numerically. Carriker acknowledged that much needs to be learned of species' ecology and life histories, and that the estuarine biotope appears to be more than "just a simple overlapping of factors (an ecotone) extending from the sea and the land, but is characterized by a unique set of its own factors arising from within the estuary from the materials and forces contributed by its bounding environments."

Some of the dominant, or “true,” macroscopic biota of estuaries that Carriker (1967) named are plants – *Spartina alterniflora*, *Zostera marina*, *Ruppia maritima*, *Cymodocea mamatorium*, *Rhizophora mangle*, and *Avicennia nitida*, and invertebrates – *Nereis diversicolor*, *Balanus improvisus*, xanthid mud crabs, *Uca pugnax*, *Callinectes sapidus*, *Mya arenaria*, *Mytilus edulis*, *Modiolus demissus*, and *Crassostrea virginica*. Additionally, Carriker noted that characteristic estuarine habitats include tidal marshes, mangrove swamps, seagrasses, oyster reefs, soft clam–clam worm flats, and others. Finally, Carriker stated that: “Little is known of the sum of these effects on community structure, but they do emphasize the need to consider benthic organisms in the context of the total ecosystem rather than as an independent benthic biocenose.” This statement, made almost a half century ago, has yet to be fully realized.

Fishes are the best known of aquatic groups in a general sense, mostly due to their commercial value. Therefore, insights into “estuarine dependency” may be best revealed through their study. One reason for this is their mobility in which various life-history stages inhabit quite different environments. Winemiller (1995) reviewed fish ecology and made the point, first, that fishes are by far the most diverse vertebrates, inhabiting an incredibly wide range of aquatic habitats from pole to pole. Second, fishes are ecologically diverse, with a wide variety of food habits, behaviors, reproductive habits, physiologies, and morphologies. Third, fishes exhibit a range of life-history strategies that result from trade-offs among various attributes, including clutch and egg size; these strategies can be classified as opportunistic, periodic, and equilibrium, but a range of intermediate strategies also exist. Finally, fishes and their diversity in ecosystems can be used as “indicators” of environmental conditions.

Much attention has now been directed toward the early life histories of fishes, as this is closely related to recruitment and, therefore, of much interest to fish ecologists and to fisheries. Selection factors are of special importance Houde (1997), and in this regard Able and Fahay (1998) extended studies on juvenile stages of fishes to define “estuarine dependence,” observing that numbers of permanent estuarine residents are relatively low, presumably because estuaries exhibit extremes in environmental conditions. Estuarine fish diversity is augmented by transients, such as freshwater species that occasionally occur in estuaries and marine species that spawn at sea but whose young use estuaries as nurseries. Therefore, estuarine fish fauna includes both residents and transients and a wide range of sizes, ages, and adaptations. In addition, those species that have successfully invaded estuaries usually inhabit only a small number of broad niches, implying that larger estuaries have larger numbers of species owing to increased habitat and niche complexity.

Able and Fahay found that, of the species for which good information is available, 60% are transients, 28% are residents, 6% are infrequent, and 6% are unclassified. For juveniles, they suggested the following adaptive groups:

- Group I. Facultative estuarine breeders, species whose nurseries are either in estuaries or on the inner shelf (e.g., *Centropomus striata* and *Brevoortia tyrannus*).
- Group II. Seasonal residents, species whose adults migrate into estuaries to spawn in spring or summer (e.g., *Menidia menidia* and *Mustelus canis*).
- Group III. Anadromous species, species whose adults migrate through estuaries in order to spawn in freshwaters (e.g., *Morone saxatilis* and *Alosa* spp.).
- Groups IV–VI. Early users, delayed users, and distant spawners, species that spawn exclusively in the ocean, but the location, timing, and manner of use of estuaries by young-of-the-year juveniles vary (e.g., *Pollachius virens*, *Prionotus carolinus*, and *Mugil cephalus*).
- Group VII. Expatriates, species whose estuarine larvae come from distant spawning (e.g., *Chaetodon ocellatus* and *Monacanthus hispidus*).
- Group VIII. Summer spawners, the largest group, represented by shallow-water spawners whose larvae develop in the immediate vicinity of spawning sites (e.g., *Cyprinodon variegatus* and *Fundulus heteroclitus*).
- Group IX. Winter–spring spawners, a few species that spawn in the winter or spring (e.g., *Pseudopleuronectes americanus*).
- Group X. Migrating spawners, species that undergo spawning migrations within the estuary (e.g., *Morone americana*).
- Group XI. Species difficult to classify: species for which some populations appear to be estuarine and other populations do not (e.g., *Tautoglabrus adspersus*).

But, of these, which are truly “estuary dependent”? Able and Fahay (1998) caution that, for fishes at least, “estuarine dependence” depends on the resolution of three areas of research: (1) the need to sample well-defined areas thoroughly for habitat evaluation; (2) assessment of the effects of habitat loss; and (3) more detail on temporal and spatial use of habitats where early stages are collected. In short, a coherent understanding of the life-history factors that control the early life histories of fishes remains to be accomplished. The same no doubt holds for invertebrates. For macroscopic plants, the situation is perhaps less uncertain, as their life histories are simpler and assessments are more easily accomplished.

In sum, most truly estuarine species should typically be resistant to the extreme environmental conditions of estuaries, and/or take advantage of favorable situations when they occur; consequently, such species may not appear to have strong habitat associations. This makes difficult the strict establishment of a definition of “estuarine dependency.” Also, the seaward boundary of an “estuary” is often blurred, so that the definition of “dependency” is hampered by lack of comparative, quantitative data from offshore habitats. The easiest distinctions are for those species for which at least one stage is shown to be physiologically or behaviorally obligate, but better natural history and experimental data for most species are required for this determination. Therefore, the question “What is an estuarine species?” remains elusive for many, if not most, species. In addition, the oft-made contention that estuaries with similar habitats may support similar species assemblages seems reasonable, but may be misleading if assumptions of estuarine dependency are based on occurrence rather than in an adaptive-evolutionary sense.

Ecological Function of Biodiversity

In addition to genome, species, and ecosystem aspects of biodiversity, a fourth category must be considered, namely, "functional diversity" (Steele, 1991; see Glossary), which concerns ecological functions with respect to environmental maintenance and change. Ecological functions within the coastal zone and its estuaries are complex and variable, and they must be understood before interpretation of the composition and patterns of biodiversity is possible. Holligan and Reiners (1992) listed a number of factors that underlie the biological diversity of the coastal zone and its estuaries, first for natural processes:

Exchanges of Materials

Riverine and atmospheric export and import, groundwater exchange, and ocean-land material transport operate at various levels, but are presently poorly understood. The role of anadromous fishes in transport of organic matter has hitherto been neglected but may be essential for some systems (Hesslein *et al.*, 1991; Bilby *et al.*, 1996; Garman and Macko, 1998).

Physico-Chemical Properties

The coastal zone is a region of high energy exchange due to interactive oceanic and atmospheric forcing associated with topographical discontinuities, density gradients caused by freshwater inflows, and seasonal heat exchanges. Deltas, estuaries, and lagoons are the major sites for transformation and accumulation of organic matter and sediment, and all are highly variable spatially and temporally, so that their average conditions are not good indicators of net fluxes. Estuaries, in particular, are "sites of complex interactions, related to salinity gradients, phase transformation involving particle-water reactions, and to biological processes that cause biogeochemical transformations."

Biological Properties

Favorable conditions of light and nutrients in the coastal zone maintain high rates of primary productivity that are several times greater than for the open ocean, and even greater than for certain coastal upwelling areas; some coastal systems, such as salt marshes, mangrove swamps, mudflats, beds of aquatic vegetation, and coral reefs, exhibit even higher productivity. Some areas act as sources, others as sinks, and the nature of the coupling of primary productivity to the benthos or to open waters may determine community structure and function.

Biogeochemical Processes

Organic matter is readily reoxidized in coastal waters, but some poorly drained areas may become anaerobic. This is especially apparent in the bottom water of estuaries in summer, when temperatures are high.

Holligan and Reiners (1992) also identify present-day human activities that influence ecological functions and biological diversity:

Altered Delivery of Freshwater

Freshwater impoundment by damming has decreased total discharge into estuaries and coastal seas by about 15% from the 1950s to the 1990s, an amount equivalent to a change in sea level of $-0.7 \text{ mm year}^{-1}$. Seasonal flows have also been altered; alteration in the residence time of water in estuaries may have far-reaching effects on chemical processes.

Changes in the Transport and Fate of Suspended Matter

Coastal subsidence, sediment starvation and consolidation, and nutrient levels have all been altered by human interventions. Land clearing, especially on steep slopes, has increased sedimentation.

Chemical Modification

Nutrients, eutrophy, and blooms have become widespread and their frequency seems to be increasing. Contaminants that are of most concern include heavy metals, synthetic organic compounds, radionuclides, and hydrocarbons.

Ecosystem Modification

This takes many forms, from physical change and habitat loss to depletion of resources. The worst-affected areas are those with high human population densities, such as Southeast Asia, and along temperate coasts that have significant sources of pollutants, such as the Baltic Sea.

Finally, longer-term processes that influence biodiversity are the effects of climate change, especially in response to global warming, should that continue to occur:

Natural Variations in Climate

Many climate-change studies describe possible alterations in biotic distributions. However, rather subtle climatic changes can induce large ecological changes that reflect the sensitive nature of marine food chains to climate and to climate-dependent factors such as nutrient levels and salinity. The direct effects of climate are often difficult to distinguish from those incurred by humans.

Temperature

The largest climate changes are expected in the higher latitudes. Thus, the poleward extension of some climate-sensitive species is to be expected in case of global warming. Temperature changes can also affect behavior and physiology (e.g., reproduction, feeding and food availability, predation, and migration), so that predictions are destined to be speculative.

Wind

Wind strongly influences upwelling and stratification, thus affecting productivity through nutrient and light availability. According to most climate change scenarios, wind intensity is expected to increase.

Extreme Events

Short time-scale events are also expected to increase with climate warming, and these may induce dramatic, long-term changes. A single storm lasting <5 days can result in sand transport equivalent to two-thirds of the total for an average year. Tsunamis have had the greatest effects recorded to date.

Changes in Sea Level

Presently, sea level is rising faster than the rate during the late Holocene due to a combination of thermal expansion of seawater and melting of polar ice as climate warms. Impacts of sea level rise on deltas and estuaries are already apparent, partly because these areas are low-lying, strongly perturbed by humans, and exhibit enhanced erosion and subsidence. Natural communities of plants and animals play a crucial role in determining the response of the coastal zone to changes in sea level.

This array of effects requires the development of research programs to address hypotheses that are relevant to the ecological function of estuarine biodiversity. Among many possibilities, the following hypotheses seem fundamental (slightly modified from Solbrig, 1991):

- For species: no aspect of life history has any influence on extinction probability.
- For communities: keystone species are essential for maintaining species richness in communities under all environmental conditions.
- For ecosystems: removal or addition of functional or structural groups that produce changes in temporal or spatial configuration of landscape elements will have no significant effect on ecosystem properties over a range of time and space scales.

These hypotheses can be clarified by means of a case-by-case examination (see the Section A Case Study: The Chesapeake Bay). For example, some species seem very alike in their life histories. However, redundancy in species function may mean that diversity and function are somewhat independent of one another. Many species of benthic infauna and epifauna are extremely abundant and ecologically important in estuaries. Many feed on sediments, and those with complete alimentary canals can consolidate organic residues into often long-lived, sculptured pellets. The question is: Are species that have similar ecological requirements replaceable?

With respect to physical structure, Roy (1984) stated that the ecology of an estuary depends on the geological stage it has reached in its evolutionary progression, and that the rate and direction of natural change provide a yardstick to assess impacts induced by humans. However, as Roy emphasized, factors influencing estuary development include (1) inherited factors, mainly of a geological nature, that control the size and shape of the basin and the nature of the sediment supply, and (2) contemporary factors of a process nature (such as tides, river discharge, waves, etc.) that influence modes of sedimentation, hydrodynamics, and the biota. This prompts the question: to what extent are structure and biodiversity related?

Mann (1982) observed that, in general, estuaries are more productive than adjacent shelf systems, bringing up relative

rates of nutrient flushing; that is, many estuaries tend to act as nutrient traps and others may be enriched by pollution. The New York Bight is a spectacular example of enrichment of a large shelf area well beyond the Hudson River's mouth. Within 600 km² of sea at the apex of the Bight, phytoplankton production amounted to about 370 g C m⁻² day⁻¹, compared with only 100 g C m⁻² year⁻¹ at the edge of the shelf. Mann and Lazier (1991) also noted that the dynamics of coastal waters, including estuaries, are made complex by: (1) shallowness, resulting in relatively mixed water that may extend to the bottom, and dead biological material that may accumulate to release nutrients that are carried rapidly to surface waters; (2) tidal currents that create turbulent mixing, which has especially marked effects on food particles, fertilization of planktonic eggs, and larval dispersal; and (3) barriers to convection imposed by coastlines, meaning that wind drives surface water away from the coast, and upwelling is the only way for it to be replaced, bringing nutrients to the surface. The question here is: to what extent are enrichment and/or pollution and circulation related to biodiversity?

Turning to larval transport, a variety of organisms have adapted to the seaward flow of low-salinity water and a compensatory landward flow of bottom water in estuaries. Organisms can make vertical migrations to maintain themselves in an estuary or to enter or to leave it seasonally. For example, estuarine larval transport and retention mechanisms are evident on two scales: large-scale, regional circulation patterns and small-scale, local water motion. There is evidence that oyster larvae (*Cr. virginicus*) rise into the water column to be carried upstream, and that this is cued by increasing salinity associated with increasing upstream flow; larvae of the blue crab (*Ca. sapidus*), however, occur in maximum numbers in surface waters at the mouth of Chesapeake Bay at night as the salinity falls on the ebb tide (Boicourt, 1982). From this and other evidence, it has been concluded that the crab larvae develop offshore, and then reinvade as larvae or juveniles. Fishes have also been shown to vary their depths, some rising into surface waters during flood to remain in the estuary, and others doing the opposite to be taken out to sea. Thus, many invertebrates and fishes utilize the two-layered estuarine structure for retention or dispersal, and this may not be entirely passive, as has often been assumed. Despite improved knowledge, Boicourt's conclusion remains pertinent, that larval transport and retention "stands at the state of the art in both physical and biological fields," which become particularly relevant to recruitment into fisheries. The question is: does recruitment depend on return or retention as the operative process, and to what extent do larvae determine their own fates?

As another example of the importance of functional diversity, juveniles of the five species of Pacific salmon (*Onchorhynchus* spp.) vary in time spent in estuaries, but for all of them a high proportion of prey tends to be detritus feeders (Healey, 1982). This means that the configuration of the estuary and entrapment efficiency of detrital matter are important elements of juvenile salmon habitat. Retention of detritus is enhanced by restricted exchange with the ocean and low bed-load transport. Marshes and submerged aquatic vegetation are efficient detritus traps, and these habitats also shelter salmon from predation. Thus, it may be hypothesized that the complex of intertidal marshes, tidal creeks and secondary river

channels, lower intertidal and subtidal weed beds, and basin morphology all contribute to the carrying capacity of the estuary for young salmon, and that appropriate estuarine configurations must be conserved if salmon production is to be maintained. The question here concerns how the complexity of the land-seascape enhances biodiversity, and how this may operate differently for closely related species.

From these examples, it is apparent that, insofar as ecosystem functioning is concerned, the addition or deletion of species, structural groups, or essential processes can have profound effects on the capacity of an estuary to maintain its biodiversity. This is especially true for “keystone” species, which have influences out of proportion to their density or biomass. Likewise, the fragmentation and/or simplification of habitats and of land-seascapes may have profound effects on estuaries, since these impacts strongly affect ecological complexity and community structure and function. Furthermore, it is likely that the functional autonomy of estuaries depends on their size and the time intervals of various processes. That is, the degree to which an ecological system may be autonomous depends on the extent to which it is independent of the ecological dynamics outside its domain. Of course, no ecosystem can be completely independent owing to the climatic, ecological, and geological connections among all portions of Earth. However, the larger the domain, the more it may tend to be autonomous during restricted time spans of investigation. Obviously, the elucidation of autonomy for a domain of a given size is a complex matter. However, the simple fact is that under many management regimes, autonomy may be incorrectly assumed.

A Case Study: The Chesapeake Bay

Chesapeake Bay is one of Earth’s largest estuaries. Its origin is that of a drowned river valley. This is the case for many estuaries associated with coastal plains, wherein the dominant processes are sedimentary and erosional and whereby the bottom is largely soft sand and mud.

The largest estuary in the U.S. and among the most complex and most productive in the world is Chesapeake Bay. This funnel-shaped estuary has the highest land-drainage to surface-area ratio of almost any other coastal water body; its 166,000 km² watershed dwarfs the 6500 km² water surface. Eight major river systems feed freshwater and terrigenous products into subestuarine systems that empty into the Bay, each exhibiting unique features. Extensive marshlands, sea-grasses, and shellfish beds support a diversity of fish and shellfish that historically made the Bay one of the world’s most commercially productive aquatic areas. Abrupt climatic events, seasonal change, changing mixes of salt and fresh water, and a varied biota have created what has appropriately been termed a “complex adaptive system” (Levin, 1998).

The Algonquian native word “Chesepiooc” became interpreted to mean Great Shellfish Bay, singling out its major historic feature – the oyster fringing reef (Figure 1), formed by a single species, the eastern oyster (*Cr. virginicus*). From a structural point of view, oyster reefs represent unique and dominant biogenic structures. These reefs’ distribution and structural features in the 1870s (McCormick-Ray, 1998)

indicate their ecological importance and functional diversity as nodes of intense biological activity, connectance through hydrological corridors, and as habitat attractors for estuarine species (McCormick-Ray, 2005).

Numerous scientists for more than a century of observation and study have cautioned against the depletion of oysters, the loss of which could impact biological, hydrological, erosional, and sedimentary patterns and processes, with major influences on functional biological diversity. A review by Rothschild *et al.* (1994) stated that “considerable concern is voiced regarding Chesapeake Bay water quality and the effects of disease on oysters” and that “the effects of a diminished oyster population abundance certainly must have changed the ‘ecology’ of Chesapeake Bay, and these effects must have become evident at the time of maximum stock decline (1884–1910).” Modern studies provide evidence of functional impact (Dame *et al.*, 1989; Ulanowicz and Tuttle, 1992; Lenihan *et al.*, 2001; Lehnert and Allen, 2002; Grabowski, 2004; Kirby and Miller, 2005).

To better understand the ecosystem effects of oysters and oyster reefs, one must begin at the regional scale, wherein the coastal zone is conceived as a nested hierarchical system (Figure 2). The regional scale is that of biogeographic and physiographic provinces. The mesoscale is represented by major regional subdivisions, such as watersheds, estuaries, coastal islands, lagoons, and coastal-ocean fronts that separate major marine regimes. The smallest scale is that of the interacting mosaics of land-seascapes, for example, wetlands, hard and soft bottoms, and water masses distinguished by salinity, temperature, and density. This hierarchy indicates top-down physical “controls” and bottom-up “feedbacks,” and places estuaries in a central role. The biogeographic province (and/or “region”) is an area whose limits are defined by the relative homogeneity of the biota. For example, the traditionally accepted boundaries for the biogeographic Virginian Province are Cape Cod, MA, and Cape Hatteras, NC. These capes are significant points of deflection for major ocean currents, principally the warm, north-flowing Gulf Stream and the cold, south-flowing Labrador Current. At these capes, dramatic changes occur in coastal characteristics, such as water temperatures and circulation patterns, and these physical features play major roles in determining the biogeographic ranges of biota. One major feature of the Virginian Province is the presence of very large estuaries, such as the Chesapeake and Delaware bays.

Species’ ranges respond to these large-scale ocean boundaries, as well as to species’ physiological and behavioral adaptations. Fishes are a case in point. Of the almost 1100 East Coast fish species, 556 species presently occur in the Virginian–Carolinian region (Ray, 1997; Ray *et al.*, 1997). Estuary-dependent species are drawn from this species pool. As discussed earlier (*see* Estuarine Biodiversity), “estuary-dependent” usually has been interpreted very broadly. Occurrence and even abundance of fishes in estuaries do not necessarily infer “dependence.” Rather, a species must be truly “obligate” in an evolutionary, adaptive sense for this definition to apply; that is, if estuaries were removed, “dependent” species, i.e., those that require estuaries as habitat at some life-history stage, would be at risk of significant depletion, even to the point of local or regional extirpation. According to

Figure 1 Historical fringing reef of Chesapeake Bay, with the Tangier Sound complex located in box. Reproduced from Ray GC, Hayden BP, McCormick-Ray MG, and Smith TM (1997) Land-seascape diversity of the U.S. east coast coastal zone with particular reference to estuaries. In: Ormond RFG, Gage JD, and Angel MV (eds.) *Marine Biodiversity: Causes and Consequences*, pp. 337–371. Cambridge, United Kingdom: Cambridge University Press.

Figure 2 A hierarchical concept of coastal zone relationships, showing top-down “controls” and bottom-up “feedbacks” of coastal zone interactions, involving levels from biogeographic provinces, to estuaries, to the oyster reef. The Virginian biogeographic province provides the species pool from which estuaries may draw “estuary-dependent” representatives. This biota is influenced by the morphometrics of individual estuaries, leading to different species communities among the estuaries of the biogeographic region. The oyster plays the role of a “keystone” species both biologically and ecologically, as the reef it builds provides habitat and may influence the morphometrics of the estuaries in which it occurs. Overharvesting of oysters in the Chesapeake Bay and elsewhere is suggested to have had major effects on estuarine function, structure, and probably biodiversity. Reproduced from Ray GC, Hayden BP, McCormick-Ray MG, and Smith TM (1997) Land-seascape diversity of the U.S. east coast coastal zone with particular reference to estuaries. In: Ormond RFG, Gage JD, and Angel MV (eds.) *Marine Biodiversity: Causes and Consequences*, pp. 337–371. Cambridge, UK: Cambridge University Press.

this definition, 151 species (27% of 556 Virginian species) qualify as “estuary dependent.” This figure is remarkably consistent with the results of Able and Fahay (1998: see Estuarine Biodiversity). This finding brings up the question: How might changes in estuaries, human-caused or not, influence the composition of these fish assemblages? For insight into an answer, we must examine the dynamics of estuaries themselves.

Many factors interact to characterize an estuary. Among these are drainage and basin area, salinity, tides and mixing, depth, dimension, water column stratification, floods, habitat types, anoxia, and many others. A principal components analysis (Ray *et al.*, 1997) revealed five components that may influence biological diversity: estuarine dimensions, dominance of marine processes, codominance of marine and freshwater processes, fjord-like attributes, and surface area. The interplay of these factors may be used to classify estuaries into the following types: (1) those that are long and wide with extensive catchment areas; (2) large, embayed, well-stratified estuaries with extensive seawater zones; (3) marine-dominated, deep, and well-stratified estuaries; (4) long and narrow, fjord-like estuaries, with large tidal prisms; and (5) estuaries with large surface areas. Chesapeake Bay falls somewhere between categories (1) and (2).

Based on what we know of the natural histories of biota, it seems reasonable to assume that these estuarine types would host different communities of species, and that different disturbance regimes would differentially affect estuarine types and their species’ communities. The obvious conclusion is that biotic communities differ among estuaries, and seasonal or weather-related changes in salinity and other factors will be reflected by variable biotic pattern. Also, because the great majority of estuarine fishes also occur over the continental shelf, fluctuations of estuarine fish communities would also be reflected by alterations of shelf-fish communities. But this cannot explain what might be the ecological consequences of these alterations, or whether the ecological role that any organism may play might be lost following that species decline. Clearly, the decline or removal of a foundation species (e.g., oyster reefs), will influence the biological diversity of the system by influencing environmental conditions through environmental feedbacks across scales. However, what might be the effect of declining fishes?

Hypothetically, changes in fish communities have also had ecological effects; how might their roles be conserved? For example, Chesapeake Bay is host to eight abundant species of filter-feeding Clupeid fishes: Atlantic thread herring (*Opisthonema oglinum*), gizzard shad (*Dorosoma cepedianum*), Atlantic menhaden (*Br. tyrannus*), Atlantic herring (*Clupea harengus*), American shad (*Alosa sapidissimus*), hickory shad (*Alosa mediocris*), alewife (*Alosa pseudoharengus*), and blueback herring (*Alosa aestivalis*). These fishes seem to have evolved opportunistic, metapopulation life styles comprising a guild in which these species complement one another in terms of responses to environmental conditions, and in which the ecological function of planktivory of this guild is not likely to be severely compromised under normal scenarios of environmental change (Ray, 2005). Another guild for sciaenids (benthic-feeding croakers) is likely. Thus, it seems reasonable to visualize Chesapeake Bay and other estuaries as composed of diverse species guilds, such that ecological function is conserved, and so is the resiliency of the estuarine system – at least, until severe environmental impacts occur.

For the Chesapeake Bay, oyster reefs are especially critical because they form hard bottom structures that interact with hydrology and influence biodiversity at many levels (McCormick-Ray, 1998). The location of these reefs is not

accidental, reflecting patterns in salinity, hydrology, and geometry of the estuarine basin, tidal stream channels and meanders, and other basin-wide factors. Reefs also influence estuarine development, sedimentation, and water clarity, and thus the formation of other habitats (e.g., submerged aquatic vegetation, marshes, soft bottoms, and hard bottoms) for a host of organisms. And as climatic, interannual, and inter-seasonal changes mobilize variable hydrologic conditions, the role of rooted and cemented estuarine habitats such as oyster reefs, seagrasses, and marshlands together play interdependent roles in providing shelter, stability, and predictable habitat. This may be of fundamental importance to functional development of the estuarine land-seascape. In sum, the eastern oyster appears to be a classic example of a “foundation” species at the level of the estuarine ecosystem. Similarly, the role of fish communities must not be overlooked.

Another type of functional feedback concerns the fact that many species exist in a number of separate populations, either as young or as adults, that mix together seasonally especially in nonreproductive periods. A common pattern of estuarine-associated fishes, for example, is estuarine or coastal spawning followed by juvenile egress from estuaries or larval ingress into estuaries with settlement by juveniles in nursery habitats. As estuarine-associated species use a diversity of habitats for reproduction, growth, and recruitment, these patchy populations at other times assemble as metapopulations or contingent memberships (Secor and Rooker, 2005; Secor, 1999). For example, an estuary-dependent species such as menhaden, which is distributed patchily among individual estuaries as juveniles, assembles over the shelf to form one or more metapopulations as adults (Figure 3). These shelf metapopulations join those of other species to become part of the shelf “metacommunity.” It follows that fluctuations of any one metapopulation within any one estuary will affect the total “metacommunity” to a greater or lesser extent (Ray, 1997). This form of large-scale biodiversity centers on community composition, not necessarily on the presence or absence of individual species, but may be strongly affected by functional alterations of estuaries. Observing the collection of species in patterns of communities leads to the conclusion that at the scale of the large, regional ecosystem, each estuary with its community components may be conceived in terms of connectivities to the sum total of estuaries responsible, to a greater or lesser degree, for the overall functional dynamics of the biogeographic region. This large-scale perspective fuses scientific concepts of landscape ecology with metapopulation theory.

The concepts presented in the case of the Chesapeake Bay suggest controls and feedbacks among organisms and the environment at several scales. One fundamental factor seems clear: east coast estuaries have been perturbed in many ways, and one of the most dramatic for the Chesapeake Bay has been the depletion of oyster reefs and some fishes, for example, shad, and the practical eradication of their functional ecosystem roles. Although data are lacking to explain beyond doubt what changes have been perpetrated by these biodiversity losses, it seems apparent that at the very least they have left a marked effect on the entire Bay system. Furthermore, it may be that these effects have cascaded up-scale to affect the adjacent continental shelf.

Figure 3 The concept of estuarine metapopulations and shelf metacommunities. Oyster reef metapopulations influence estuarine morphometrics and biodiversity. Consequently, the fish biota of various estuaries influence the fish metacommunity of the shelf.

Future Challenges

We make three points in conclusion. The first concerns the need for greatly increased attention to the natural histories of estuarine and shelf species, which underlie both theory and management practice. The minimal requirements for informed conservation and management are descriptions of species' life histories in the context of their environmental relationships.

Second, many estuarine organisms range widely and form metapopulations over the shelf, as components of estuary-shelf communities. Thus, the minimal scale for sustainability of biodiversity becomes that of the biogeographic region. Quantitative, landscape-level descriptions of the regional coastal zone, including estuarine habitats, are a necessary prerequisite for conservation and management.

Third, it has become a truism in ecology that no one scale adequately describes ecosystem phenomena. Rather, the interaction among phenomena on different scales must become the centerpiece of research and management. This strongly suggests that explanations for fluctuations in biodiversity, including those within biotic communities and at regional scales, will continue to be obscure until multiscale ecosystem functions are better understood. Ecosystem-based management is the logical outcome of interdisciplinary, multiscale knowledge. This recognizes that understanding the

ecology and diversity of coastal zone biota depends in large part on understanding land–sea and estuarine interactions, and also on the joint application of metapopulation and land–seascape theory and methods.

The National Research Council (NRC, 1995) stated that a major future research objective is “to understand the patterns, processes and consequences of changing marine biological diversity by focusing on critical environmental issues and their threshold effects, and to address these effects at spatial scales from local to regional.” This objective cannot be met absent a specific consideration of estuaries as major, scale-dependent pathways of biotic and abiotic interchanges. Estuarine biodiversity, structure, and function have been severely modified by humans around the globe. Nevertheless, many estuaries remain either good candidates for restoration and/or relatively rich, productive, and resilient. Documentation of impacts is severely hampered by lack of long-term baseline information, inadequate assessment of biodiversity, lack of trained taxonomists, and difficulty in sampling. Nevertheless, an extensive estuarine literature is now available, illustrating that control of pollution, development, excessive natural resource extractions, and changes in ecosystem function urgently need to be addressed. Problems may not be eliminated, only ameliorated, but increased understanding is essential for the future sustainability of estuaries. Carriker (1967) put the matter boldly more than four decades ago: “There is consequently an urgency to study estuaries before unenlightened defacement obliterates them and before it becomes expedient to investigate them primarily as outdoor pollution laboratories.”

Glossary

Biome A large-scale complex of ecosystems sharing similar climate and large-scale natural disturbance regime, resulting in high similarity of vegetation structure.

Ecological biodiversity Variety of biotic communities (plant, animal, and microbial communities) and their complexes (ecosystems, landscapes, and biomes).

Formation Large-scale (subcontinental or continental) vegetation complex defined primarily on the basis of a combination of dominating life-forms (hence, vegetation structure).

Habitat A place of dwelling of a biotic community (or a complex thereof) showing a particular combination of ecological factors occupying a certain area in a certain period of time.

Orobiome Mountain range characterized by a particular climatic pattern and a characteristic sequence of vegetation zones.

Syntaxon (plural syntaxa) A category of vegetation typology based on the floristic–sociological approach (known also as the Braun–Blanquet approach); the basic syntaxon rank is association, which further groups into alliances, which group into orders, and orders group into classes.

Vegetation mapping Scientific activity aimed at capturing the spatial extent of the vegetation types on a map.

Vegetation megazone Large-scale vegetation complex characteristic for a zonobiome.

Vegetation survey Product of research activity aimed at the description and classification of vegetation cover on various levels of complexity in a certain geographic area using various field and data-evaluation methods.

Zonobiome Broad ecological topographical unit characterized by a certain climatic pattern.

Introduction

Hardly any place in the world supports in a relatively small area such a variety of countries, peoples, cultures, histories, languages, political views, cuisine, and types of cheese and wine as does Europe. There might be more languages and people in India, higher species diversity of plants in the tropical rain forest of Columbia or Brazil, or more diverse cuisine in China, but there is only one Europe.

Europe's nature is showing many faces, both pristine ones in the form of tracks of tundra and forests and created (or miscreated) ones – those carrying the signs of human activities. Europe is a patchwork of ecosystems connected by an intricate net of gradients of ecological factors ranging from those controlling continental patterns of vegetation megazones and biomes to local gradients creating small-scale mosaics of biotic communities.

This article discusses the variability of European ecosystems and a major framework of biodiversity patterns at various scales of complexity.

Europe is a continent, a large chunk of land; therefore, the author discusses this subject from the viewpoint of the diversity of large-scale ecological units such as vegetation megazones and biomes. The terrestrial habitats (and their complexes) will dominate this discourse and the author emphasizes the diversity of vegetation assemblages, which are traditionally considered the core of the structure and functioning of all terrestrial ecosystems.

Europe is approximately 10 million km² and spans 35–81° N of latitude and 60° E–10° W of longitude. Although Europe is the second-smallest continent (7% of the world's land surface), the basic classification of ecosystem diversity

can be discussed only at a very large scale of biome. Not only the limited extent of this article but also the extraordinary wealth of scientific knowledge collected over centuries and the diversity of the subject impose constraints on the level of detail and accuracy of this discourse.

Ecosystem Diversity: Concepts and Approaches

Ecosystem, often defined as the union of biotic community and its environment, presents an obvious difficult scaling problem. Ecosystems as real entities occur in space and time. Depending on the conditions, one can recognize natural or artificial borders allowing the classification of ecosystems, an exercise meant to set a framework for simplifying the complexity of ecosystems and featuring them in a synoptic way.

Classification of Vegetation

Most European ecosystems are obviously terrestrial ecosystems accompanied by semiterrestrial and aquatic ones. Vegetation (defined as the unity of plants occupying a certain area in a certain time) is the major biotic element of terrestrial ecosystems. Hence, the problem of classifying terrestrial ecosystems is a problem of classification of vegetation.

The approaches to the classification of vegetation are manifold and largely depend on the criteria (and their weighting), aims, and means (Mucina, 1997a). Several basic approaches to the classification of vegetation have emerged during the past century (Whittaker, 1978). Among these, the floristic–sociologic approach (Westhoff and van der Maarel, 1978) became a standard communication tool among

European (and other) vegetation scientists involved in or harvesting fruits of vegetation classification exercises.

Floristic–Sociologic Approach to Vegetation Classification

The basis of the floristic–sociological approach to the classification of vegetation is the notion of the total floristic composition and the notion that some species indicate the environmental conditions better than others. These are called diagnostic species (Braun-Blanquet, 1964). Vegetation stands are selected by following various criteria, among which the so-called representativity of the studied vegetation type is the leading one. This approach is aimed at the recognition of plant communities – plant assemblages recurrent in space and in time and showing a distinct floristic composition that reflects certain combinations of current and past habitat conditions. The basic vegetation unit of this approach is the so-called association, a theoretical construction that is a result of the abstraction classification process involving many vegetation stands. A hierarchy of vegetation units based on groups of species having similarity between plant communities and their groups is also a vital part of the floristic–sociological approach. Floristically and ecologically similar associations are grouped into alliances, the alliances are grouped into orders, and the orders are grouped into classes. The vegetation classes can be less formally grouped into divisions. Particular associations, alliances, orders, classes, and divisions are termed syntaxa (Westhoff and van der Maarel, 1978) of various ranks and build the syntaxonomic hierarchy. An elaborate, highly formalized system of rules has been introduced to govern the formation of names of the syntaxa.

Dominance Approach to Classification of Vegetation

Another approach to the classification of vegetation emphasizes the role of the dominant species or dominant growth forms, marking a departure from using plant taxonomy as the currency. Without discussing this approach in great detail (Whittaker, 1978), the notion of formation is the core tool of the dominance approach. The formation is the vegetation component (thus, in terrestrial ecosystems it is the leading element) of the concept of biome. Although the floristic–sociological approach is well suited for the classification and description of vegetation on small geographic scales, formation and biome are, for the same purpose, well suited on large scales (subcontinental and continental).

Classification of Habitats

Despite much critical challenging of some subjective points regarding the criteria for selection of stands and criteria of weighting of species in the classification process and sometimes awkward nomenclature, the floristic–sociological approach is aimed at enhancing the effectiveness of communication when addressing units of vegetation cover. It is therefore not surprising that it was the terminology and concepts of this approach that were adopted as the basis of the majority of the units of the habitat systems developed for various purposes by the former European Communities (now European Union) authorities.

The classification of habitats passed several stages of development, spanning CORINE habitat classification (Commission of European Communities, 1991), Palearctic habitat

classification (Devillers and Devillers-Terschuren, 1996), and EUNIS3 habitat classification (Davies and Moss, 1998). Obviously, the purpose of habitat classification is a practical one. It should serve (and serves) important purposes by the delimitation and evaluation of land-use characteristics, projection and management of nature reserves of other areas of special nature conservancy interests (e.g., the Natura 2000 network of Special Areas of Conservation), etc. Not surprisingly, such a habitat classification scheme is a legal standard within the borders of the European Union.

Biodiversity of Habitats and Vegetation

Sources

The current vegetation landscape of Europe is a result of manifold forces forming and reforming the habitat networks during the past few thousands of years; undoubtedly, some features of this habitat and vegetation patchwork are very old. One can hardly avoid using oversimplification when talking about the sources of community (including vegetation and animal communities) and ecosystem diversity of present-day Europe. The author distinguishes four major prerequisites to the community and ecosystem diversity (Table 1):

1. Taxon diversity: Plant and animal communities are composed of individuals belonging to several (often many) taxa. Speciation and associated processes of within-taxon diversification in addition to migrations of taxa – either ancient, natural ones or current ones largely driven by human activities – are the major sources of taxon diversity.
2. Habitat diversity: Habitats are homes of biotic communities and the greater the variety of habitats, the greater the variety of biotic communities populating them. The nature of habitats is determined primarily by ecological factors – their characteristics and dynamics. Regardless of whether one considers spatial or temporal scales, one can recognize geological, geomorphologic, and soil-formation processes accompanied by hydrological dynamics and

Table 1 Prerequisites and sources of the ecosystem and community diversity

<i>Prerequisite</i>	<i>Sources</i>
Taxon diversity	Speciation Extinction Migrations
Habitat diversity	Geological processes Geomorphological processes Soil-formation processes Hydrologic dynamics Climate change
Diversity of biotic interactions	Competition and related negative interactions Facilitation and related positive interactions
Diversity of human interference	Disturbance and removal of habitats Creation of new habitats

climate changes as the major natural sources of the habitat diversity.

3. Diversity of biotic interactions: The individuals representing different taxa interact within the biotic communities in many ways. They may compete for resources, facilitate each other's growth and reproduction by a plethora of positive interactions, and may behave differently. Undoubtedly, the biotic interactions form the face of each community and thus contribute to ecological diversity.
4. Diversity of human interference: Humans have made themselves the center of the universe and from this point of view have also become the dominant source of the disturbance (up to complete removal) but also creation of new habitats and new biotic communities through manipulating ecological factors and facilitation of species migrations.

Patterns

Biomes of Europe

Europe has six (of the world's nine) zonobiomes as defined by Heinrich Walter (Walter and Breckle, 1991; pp. 22–25). These include, from south to north, Mediterranean zonobiome (IV), warm-temperate zonobiome (V), nemoral zonobiome (VI), continental zonobiome (VII), boreal zonobiome (VIII), and polar zonobiome (IX). Furthermore, many zonoecotones mediate between the particular zonobiomes and these are designated as IV–V, V–IV, V–VI, VI–VII, VII–VI, VII(III), VIII–VI, and IX–VIII. The zonoecotone III–IV, mediating between subtropical zonobiome (not represented on the continent) and Mediterranean zonobiome, is found on the Canary Islands.

Following the combined approach to define biomes using climate and vegetation structure, one can tentatively recognize 10 biomes in Europe, the Canary Islands and the Azores. (Table 2).

Surprisingly little attention has been paid to the definition of extant European biomes in comparison with other parts of the world. This can, to a huge extent be attributed to traditions in classification of ecosystems in Europe. The dominance-based approach to the classification of vegetation leading directly to the definition of biomes when exercised on a large scale is the predominant approach in parts of the world in which there is a lack of advanced knowledge on flora. Europe

is undoubtedly a region in which the flora-based approach has a long and firmly rooted tradition.

Diversity of Vegetation Types

To list all syntaxa described in Europe is impossible at this stage and here. A recent account of the high-rank syntaxa (Mucina, 1997b; Rodwell *et al.*, 2002; and an unpublished checklist of high-rank syntaxa by Mucina L and 24 collaborators) revealed that the European vegetation can be classified into 88 classes (of which eight are endemic to Macaronesian Islands), 248 orders, and 945 alliances (these counts exclude the Azores and Caucasus). Table 3 provides a list of the classes and comments on their zonality status. The number of associations is unknown, although one estimate suggests there might be as many as 3000. For further details on the diversity of syntaxa occurring in various European countries, refer to the many national vegetation surveys (and transnational vegetation accounts) listed in Table 4.

Several interesting biodiversity patterns can be observed within the groups of syntaxa, including classes, orders, and alliances (Table 3):

1. The zone of the Temperate Deciduous Forests is the dominating biome of Europe, both spatially and in the number of syntaxa characterizing the natural, postglacial forests and associated scrub, but also secondary vegetation types (such as grasslands and man-made vegetation) replacing the forests in cultural landscapes of Western, central, and Eastern Europe.
2. The Mediterranean region (supporting the Mediterranean biome and Mediterranean orobiome) shows a high concentration of classes and subordinated syntaxa. This can be partly ascribed to high gamma diversity (richness of regional floras), high regional and endemism as a result of the insular character of many types of Mediterranean habitats and last but not least to due to the high concentration of refugia across the Region. Not only are numerous true marine islands very abundant within the Mediterranean but also the mountain summits form an archipelago of their own, demonstrating their own rates of evolution and combination of ecological and biogeographical factors leading to specific plant assemblages.
3. The high-latitude regions (arctic and boreal zones) show lower diversity of vegetation types partly as a result of low extant gamma diversity (regional species pools), being a result of repeated glacial-cycle disturbance resulting in

Table 2 Preliminary scheme of European biomes with corresponding Walter's zonobiomes

Biome	Zonobiome or zonoecotone	Comment
Arctic Desert Biome	IX in part	Northern Europe, Arctic islands
Tundra Biome	IX in part; IX–VIII	Scandinavia, northern Russia
Boreal Forest Biome	VIII; VIII–VII; VIII–VI	Scandinavia, Russia
Steppe Biome	VII; VI–VII	Ukraine and Russia
Temperate Deciduous Forest Biome	VI; VII–VI	Most of western and Central Europe
Mediterranean Biome	IV; IV–V	Entire Mediterranean basin
Warm-Temperate Evergreen Forest Biome	V; V–VI	Macaronesia, Colchis (Transcaucasus)
Warm-Temperate Semidesert Biome	III–IV	Canary Islands, southern Spain?
Continental Semidesert Biome	VII(III)	Around Caspian Sea

Table 3 Zonality and azonality status of European phytosociological classes and their correspondence with the biome and orobiome classification scheme

<i>Classes</i>	<i>O</i>	<i>A</i>	<i>Diagnosis</i>	<i>Note</i>
<i>I. Zonal vegetation</i>				
<i>I.A. Tundra Biome</i>				
Loiseleurio-Vaccinietea	1	7	Arctic-boreal tundra scrub and (sub)alpine dwarf-scrub	Relictual in Nemoral Orobiome
Carici-Kobresietea	2	6	Circumarctic dwarf-scrub and graminoid chionophobous tundra and relict wind-exposed alpine short grasslands on base-rich substrates	Relictual in Nemoral Orobiome
Salicetea herbaceae	1	6	Arctic and alpine-subnival vegetation of long-lasting snow-beds and slopes irrigated by melt waters	Relictual in Nemoral Orobiome
<i>I.B. Boreal Forest Biome</i>				
Vaccinio-Piceetea	3	9	Holarctic coniferous forests on acidic soils of boreal zone and high-altitudes of Nemoral Orobiomes	Also in Nemoral Orobiome and relictual in Mediterranean Biome
Pyrolo-Pinetea	2	2	Euro-Siberian (sub)continental thermophilous pine forests on deep sands on exposed rocky outcrops	Relictual in realm of Nemoral Biome
Roso-Pinetea mugo	1	3	Subalpine krummholz of mountains of Central and south-western Europe	
<i>I.C. Temperate Deciduous Forest Biome (Nemoral Biome)</i>				
Carpino-Fagetea	6	28	Mixed broad-leaved deciduous forests on eutrophic, anhydromorphic soils temperate zone of Europe	
Quercetea roboris	2	9	Acidophilous oak, oak-birch and beech forests on nutrient-poor soils	
Quercetea pubescentis	3	24	Thermophilous (semi)deciduous oak forests of submediterranean provenience	
Brachypodio-Betuletea pendulae	1	3	Hemiboreal pine and birch-pine open grassy forests on fertile soils of the South Urals and southern Siberia	
Erico-Pinetea	4	9	Relictual pine forests and related scrub on calcareous and ultramafic substrates	
Rhamno-Prunetea	5	23	Shrubland vegetation seral or marginal to broad-leaved forests of the nemoral zone of Europe	
Lonicero-Rubietea plicati	1	2	Acidophilous scrub, hedges and scrub of forest clearings on dry sandy, nutrient-poor soils of Western Europe	
Calluno-Ulicetea	3	18	Dwarf-shrub and mat-grass heaths on acidic soils from the planare to montane belts	Also marginally associated with Boreal biome
Koelerio-Corynephorotea	6	24	Pioneer vegetation on primitive soils and rocky outcrops in regions with mild winter climate	Also marginally associated with Boreal biome
Molinio-Arrhenatheretea	12	36	Secondary mesic and wet meadows on fertile soils	Also marginally associated with Boreal biome; relictual or azonal within Mediterranean biome
Trifolio-Geranietea	3	13	Thermophilous woodland fringe and tall-herb vegetation of nutrient-poor sites in the submediterranean to subboreal zones of Europe	Also marginally associated with Boreal, Steppe and Warm-Temperate Evergreen Forest biomes
<i>I.D. Steppe Biome (Temperate Grassland Biome)</i>				
Festuco-Brometea	11	49	Dry grassland and steppe vegetation of mostly base-rich soils of the submediterranean to the hemiboreal zones of Europe	Relictual in realm of Nemoral and Mediterranean biomes
Festucetea vaginatae	1	6	European continental steppes and dry grasslands on sandy soils	Relictual in realm of Nemoral Biome
Festuco-Puccinellietea	6	29	Saline steppes and secondary steppic grasslands of the continental regions of Eastern and Southern Europe	Relictual in realm of Nemoral Biome (especially in the leso-steppe zone)

(Continued)

Table 3 Continued

<i>Classes</i>	<i>O</i>	<i>A</i>	<i>Diagnosis</i>	<i>Note</i>
<i>I.F. Mediterranean Biome</i>				
Quercetea ilicis	3	23	Mediterranean maquis, pine, and oak forests and associated sclerophyllous scrub	Relictual in realm of Nemoral Biome
Rosmarinetea officinalis	5	17	West and Central Mediterranean scrub (tomillares, esplugueras, romerales, matorrales, garrigue) on calcareous substrates	
Cisto-Micormerietea	2	7	Thermo- to supramediterranean phrygana and garrigue of the Central and Eastern Mediterranean	
Cisto-Levanduletea	2	7	West and Central Mediterranean scrub (jarales, matorrales, garrigue, phrygana) on acidic siliceous and ultramafic substrates	
Onosmo-Ptilostemetetea	2	4	Mediterranean garrigues on raw flysch and lime-rich substrates of the Euxinic seabords	Endemic to the Black Sea region
Cytisetea scopario-striati	2	9	West Mediterranean (mainly Iberian) broomy scrub (retamares, piornales, escobonales) and related mantle communities	
Oleo-Rhamnetea crenulatae	1	5	Macaronesian dry forest, matorral, and tomillar	Endemic to Macaronesia
Cytiso-Pinetea canarensis	1	2	Canarian pine forests and related juniper scrub	Endemic to Macaronesia
Thero-Brachypodietea	4	15	Mediterranean pseudosteppe grasslands on calcareous rocks and relic steppes on deep clayey soils	
Stipo-Agrostietea castellanæ	2	4	Ibero-Atlantic and Madeiran meso- to supra-mediterranean perennial grasslands	
Stipo-Trachynietea	3	19	Mediterranean calciphilous communities of annual and ephemeroïd herbs and grasses	
Helianthemetea guttati	2	18	Mediterranean acidophilous communities of annual and ephemeroïd herbs and grasses	
<i>I.G. Warm-Temperate Semidesert Biome</i>				
Kleinio-Euphorbietea	1	1	Macaronesian succulent scrub on semidesert lava beds (taibal and cardonal)	Endemic to Macaronesia (possibly Late Tertiary relict)
Pegano-Salsolitea	5	15	Thermo-mediterranean and Macaronesian halo-nitrophilous coastal scrub of (semi)arid regions	Also associated with Mediterranean biome in azonal habitats
<i>I.H. Continental Semidesert Biome</i>				
Artemisietea lerchianæ	2	5	Aralo-Caspian semideserts	
Petrosimonia-Kalidietea	2	3	Continental hypersaline scrub of edges inland saline lakes and seabords of Eastern Europe and Central Asia	Also associated with Steppe Biome (relictual?)
<i>I.I. Warm-Temperate Evergreen Forest Biome (Laurisilva Biome)</i>				
Pruno hixæ-Lauretea	3	10	Macaronesian laurisilva and related scrub	Endemic to Macaronesia (including Madeira); Late Tertiary relict
Lauro azoricæ-Juniperetea	2	3	Azorean broad-leaved evergreen laurisilva and related matle and thickets	Endemic to Azores; Late Tertiary relict
<i>II. Vegetation of orobiomes</i>				
<i>II.A. Boreal and Nemoral Orobiomes</i>				
Elyno-Seslerietea	5	22	Alpine and subalpine calcareous swards of nemoral mountain ranges	
Juncetea trifidi	5	22	Alpine acidophilous grasslands of Central European and Balkan mountains and Arctic and boreo-arctic rush swards	Also associated with Tundra Biome
Mulgedio-Aconitetea	5	20	Scrub and tall-herb vegetation at high altitudes, moistened and fertilized by percolating water	Also associated with Boreal Biome

(Continued)

Table 3 Continued

<i>Classes</i>	<i>O</i>	<i>A</i>	<i>Diagnosis</i>	<i>Note</i>
<i>II.B. Mediterranean Orobiomes</i>				
Pino-Juniperetea	2	13	Dry relict oromediterranean and submediterranean orotemperate pine forests, juniper woodlands and related scrub of the Mediterranean	
Festucetea indigestae	2	5	Iberian and North African supra- to cryomediterranean xerophilous silicicolous fescue grasslands	Endemic to Spain
Festuco-Ononidetea	2	10	Dry basiphilous supra-oromediterranean and oro-temperate submediterranean grasslands and related dwarf scrub of south-western Europe	
Carlino-Genistetea lobelii	1	2	Cyrno-Sardean oromediterranean cushion-tragacantic scrub and related grasslands	Endemic to Corsica and Sardinia
Rumici-Astragaletea	3	4	Siculo-Calabrian oromediterranean and upper mesomediterranean pulvinate scrub and related grasslands	Endemic To Italy
Daphno-Festucetea	2	6	East-Mediterranean oromediterranean calcareous xeric grasslands and tragacanthic phrygana	Endemic to Greece
<i>II.C. Semidesert Orobiomes</i>				
Spartocytisetea supranubii	1	1	Canarian high-altitude volcanic semidesert scrub	Endemic to Canary Islands
Violetea cheiranthifoliae	1	1	Canarian herbaceous high-altitude tallus vegetation	Endemic to Canary Islands
<i>III. Azonal vegetation</i>				
<i>III.A. Azonal aquatic vegetation</i>				
<i>III.A.1. Azonal aquatic saline vegetation</i>				
Zosteretea	3	3	Eel-grass swards on muddy and sandy substrates in the sea sublittoral and eulittoral zones	
Ruppietea maritimae	1	2	Submerged rooted communities of brackish waters	
<i>III.A.2. Azonal aquatic freshwater vegetation</i>				
Lemnetea	1	1	Free-floating duckweed communities of still, relatively nutrient-rich, fresh waters in warmer regions	
Potametea	2	8	Communities of rooted, floating or submerged plants in mesotrophic and eutrophic fresh waters	
Charetea fragilis	1	2	Submerged macro-algal (stonewort) swards	
<i>III.B. Azonal amphibian vegetation</i>				
<i>III.B.1. Azonal amphibian saline vegetation</i>				
Spartinetea maritimae	1	1	Pioneer intertidal perennial grasslands	
Thero-Salicornieteae	1	5	Pioneer intertidal communities dominated by annual succulent halophytes, rarely occurring also on banks of inland salt pans	
Salicornieteae fruticosae	2	10	Mediterranean and thermo-atlantic perennial salt-marsh scrub	
Juncetea maritimi	5	12	Perennial grasslands and herblands of coastal and inland salt-marshes and sea-cliffs	
Crypsidetea aculaetae	1	1	Pioneer ephemeral dwarf-grass vegetation of periodically flooded saline habitats in submediterranean and (sub)continental Eurasia	
<i>III.B.2. Azonal amphibian freshwater vegetation</i>				
Bidentetea tripartiti	1	2	Summer-annual, pioneer vegetation of periodically flooded edges of water bodies	

(Continued)

Table 3 Continued

Classes	O	A	Diagnosis	Note
<i>Oryzetea sativae</i>	1	1	Weed communities of rice fields	
<i>Littorelletea</i>	2	6	Pioneer ephemeral hairgrass swards and bladderwort communities in oligotrophic waters	
<i>Isoeto-Nano-Juncetea</i>	2	9	Pioneer ephemeral dwarf-cyperaceous vegetation on periodically flooded (freshwater) habitats	
<i>Montio-Cardaminetea</i>	2	10	Moss-rich vegetation of water springs	
<i>Phragmiti-Magnocaricetea</i>	3	10	Swamp and reed vegetation of fresh or slightly brackish waters	
<i>Scheuchzerio-Caricetea</i>	2	8	Vegetation of transitional mires, fens, and bog hollows	
<i>Oxycocco-Sphagnetes</i>	2	4	Holarctic ombrotrophic bog and wet heathland vegetation on acid oligotrophic peat	
<i>III.B.3. Azonal alluvial and mire forests and scrub</i>				
<i>Populetea albae</i>	2	9	Riparian gallery forests of Eurosiberian and Mediterranean regions	
<i>Salicetea purpureae</i>	1	8	Riparian willow scrub and thickets of Eurosiberian and Mediterranean regions	
<i>Nerio-Tamaricetea</i>	2	9	Mediterranean riverine scrub	
<i>Molinio-Betuletea pubescentis</i>	2	4	Azonal forest and shrub communities of mesotrophic mires	
<i>Vaccino uliginosi-Pinetea</i>	1	2	Forest and shrub communities of oligotrophic mires	
<i>Alnetea glutinosae</i>	1	1	European alder carr forests	
<i>Franguletea</i>	1	1	Willow carr communities of Western and sub-Atlantic Central Europe	
<i>III.C. Azonal terrestrial vegetation</i>				
<i>III.C.1 Azonal coastal vegetation</i>				
<i>Cakiletea maritimae</i>	3	4	Pioneer vegetation of nitrophilous annuals on strandlines of sandy and shingle beaches of Atlantic, Mediterranean and Euxinic coasts	
<i>Crithmo-Staticetea</i>	2	13	Herb-rich and dwarf-scrub vegetation of coastal salt-splashed cliffs and walls Atlantic and Mediterranean seabords	
<i>Saginetes maritimae</i>	2	6	Ephemeral winter-annual vegetation of disturbed saline coastal habitats and in inland saline badlands	
<i>Ammophiletea</i>	2	8	Coastal dune vegetation of temperate and mediterranean seabords of Europe, North Africa, Middle East and Caspian Sea	
<i>Honckenyo-Elymetes</i>	1	1	Vegetation of coastal shingle, boulders or rocky cliffs, enriched with organic detritus of boreal and arctic shores of Europe	
<i>Polycarpo-Traganetea</i>	1	2	Canarian, Cabo Verdian and West-Saharan oceanic halophilous coastal desertic dune scrub	Macaronesia and North Africa
<i>III.C.1 Azonal chasmophytic vegetation</i>				
<i>Asplenietes trichomanis</i>	16	78	Vegetation of crevices and surfaces of rocky cliffs and walls	
<i>Adiantetea</i>	1	2	Fern-rich rocky communities of water-splashed habitats	
<i>Thlaspietes rotundifolii</i>	13	48	Vegetation of scree habitats and pebble alluvia of Europe and Arctic islands	
<i>Aeonio-Greenovietes</i>	1	3	Macaronesian chasmophytic vegetation of exposed volcanic rocks	Endemic to Macaronesia
<i>III.C.1 Synanthropic (anthropogenic) vegetation</i>				
<i>Stellarietes mediae</i>	8	44	Annual weed communities of arable crops, gardens and waste places	

(Continued)

Table 3 Continued

Classes	O	A	Diagnosis	Note
Polygono-Poetea annuae	1	3	Therophyte-rich vegetation of trampled habitats	
Artemisieta vulgaris	4	14	Perennial and thistle-rich (sub)xerophilous ruderal communities of temperate and Mediterranean regions	
Galio-Urticetea	4	12	Tall-herb seminatural saum vegetation of nutrient-rich fringes of forests and scrub and of water courses of temperate Europe	
Epilobieta angustifolii	1	2	Spontaneous pioneer tall-herb vegetation of acidic soils of forest margins and clearings	

The regions covered in this list includes Europe proper, Iceland, Svalbard, Canary Islands, Madeira, and Azores. The nomenclature of classes follows so far unpublished checklist of high-rank syntaxa of Europe by Mucina *et al.* (in prep.). O, number of phytosociological orders; A, number of phytosociological alliances. The classes printed in bold (Groups I and II) are zonal (normal font) or intrazonal (italics). For correspondence of the Biomes with the Walter's zoniobiome scheme see Table 2.

dramatic impoverishment of the flora and also because of the large-scale occurrence of uniform habitat complexes, and due to adversity of climate.

- Among the azonal (and intrazonal) units, the *Asplenieta trichomanis* and *Thlaspieta rotundifolii* (classes comprising vegetation of special habitats such as rock faces, fissures, and screes) show the highest diversity of orders and alliances – reflecting the high diversity of ecological–biogeographic patterns. These two classes probably house most European local endemic species.
- The dry grasslands of the *Festuco-Brometea* (and partly also of the *Trifolio-Geranieta*) show extensive primary and secondary distribution in the steppe and leso-steppe zones (the latter constituting the transitional zone between the steppes and the forest biomes) and comprise the most species-rich plant communities of Europe. Russian steppes, for instance, can support more than 60 species per square meter. Large-scale distribution and rich regional species pools are prerequisites to high beta diversities manifested in a high number of vegetation types.
- The synanthropic (man-made and man-controlled) vegetation of Europe is also very diverse in terms of the number of syntaxa. The class of *Stellarieta mediae* comprises 44 alliances. The same pattern applies to the *Molinio-Arrhenatheretea*, comprising 36 alliances classifying secondary mesic grasslands. These numbers are indicative of the high diversity of disturbance factors related to human activities such as agriculture, silviculture, building activities, and unintentional transport of seeds and fruits over continental borders. The flora of Europe was enriched by many alien species adding to the diversity of vegetation types. Yet, personal classification bias could have inflated the number of syntaxa to an extent and more work is needed to establish the identity of these units.
- Mediterranean classes such as *Rosmarinetea officinalis* and *Quercetea ilicis* also show high diversity with regard to the number of alliances. Still higher diversity becomes obvious on the level of associations reflecting the relict nature of habitats and diversity of disturbance regimes in the Mediterranean.
- The lowest diversity of vegetation types is encountered in the classes typifying vegetation of the freshwater, marine, and coastal vegetation. Often, only a few orders or

alliances are found within classes such as *Lemnetae*, *Potametea*, *Ruppietea*, *Spartinetea*, and *Hockenyo-Elymetea*. However, on the whole, the nonterrestrial complex of habitats is very diverse, which is reflected in the high number of phytosociological classes.

Vegetation Mapping

Vegetation cover is a spatial phenomenon. Regardless of which criteria (physiognomic, structural, ecological, floristics and the like; see Whittaker, 1978) are used to classify (hence simplify) vegetation, vegetation types can be mapped – featured as a two-dimensional graphical model called a *vegetation map*. While a scientifically sound vegetation floristic-ecological classification system should carry a message on ecological (and evolutionary) assembly of the classified vegetation (and flora), a vegetation map places this message in a spatial context. It is therefore not surprising that vegetation maps are sought for as prime sources of information for making informed decisions on conservation and for providing information on biodiversity and other natural resources.

Vegetation mapping in Europe has a long tradition (reviewed by Küchler, 1963; Bohn *et al.*, 2000–2004); its development has been spurred by progress in vegetation classification. Despite political differences between countries East and West of the infamous Iron Curtain, an extensive group of vegetation scientists from almost all European countries, under the leadership of Trautmann W, Ozenda P (France), Lavrenko EM (then Soviet Union), and later joined by Neuhäusl R (then Czechoslovakia) and Bohn U (Germany), embarked in 1975 on a project to collate the existing vegetation map, support construction, and publish new ones. As a result of this unprecedented cooperation, first, a comprehensive and scientifically sound vegetation map of Europe was published 25 years after the project was conceived (Bohn *et al.*, 2000–2004). The interpretational manual to the Map (so far available only in German) contains not only a description of all more than 700 mapping units, but also the most exhaustive list of vegetation maps ever published in Europe. The publication of this Map marks an important methodical transition marked by the advent of the GIS methodology and later increased availability (and accessibility) of satellite imagery aiding the production of modern

Table 4 Major monographs and accounts of diversity of vegetation types and ecosystems in Europe

<i>Region</i>	<i>Year</i>	<i>Source</i>	<i>Comment</i>
<i>Pan-European vegetation surveys</i>			
Europe	1852	Henfrey (1852)	A classical narrative about vegetation of selected regions of Europe
	1933	Various authors (1933–1940)	Unfinished (seven issues published) series of syntaxonomic monographs; edited by Braun-Blanquet J
	1962	Lohmeyer <i>et al.</i> (1962)	List of high-ranked syntaxa of Europe
	1973	Various authors (1973–1981)	Unfinished series of syntaxonomic monographs; edited by Tüxen R
	1976	Ernst (1976)	Syntaxonomic survey of vegetation of heavy-metal substrates
	1977	Various authors (1977–1999)	Accounts on major ecosystems of the World; many review papers feature the European ecosystems; edited by Goodall D
	1984	Mayer (1984)	An overview of the forest vegetation of Europe
	1985	Polunin and Walters (1985–1992)	Popular account of major biomes and ecosystems of Europe (1992: Italian edition)
	1997	Mucina (1997)	Conspectus of vegetation classes of Europe and Canary Islands
	1998	Rodwell <i>et al.</i> (1998)	Syntaxonomic calibration of the EUNIS units; including survey of high-rank syntaxa of Europe
	2000	Bohn <i>et al.</i> (2000–2004)	First comprehensive vegetation map of Europe; 2000: legend, 2003: text and maps, 2004: interactive CD
	2001	FAO (2001)	Map of vegetation zones based on the Map of Natural Vegetation of Europe (Bohn <i>et al.</i> , 2000–2004) accompanied by brief descriptions of the zones
	2002	Rodwell <i>et al.</i> (2002)	First published comprehensive survey of high-rank syntaxa of Europe; containing a crosswalk to habitats units of EUNIS
	2010	Klötzli <i>et al.</i> (2010)	A milestone monographic account of vegetation of Europe
<i>Transnational vegetation surveys</i>			
Alps	1928	Schröter (1928)	First comprehensive description of the vegetation of the Alps
Western Europe	1939	Tansley (1939)	Monographic vegetation account of the British isles (including UK and Ireland)
Central Europe	1943	Braun-Blanquet and Tüxen (1943)	First brief account of high-rank syntaxa of Central Europe
Mediterranean	1943	Rikli (1943–1946)	Classical three-volume opus featuring vegetation of the mediterranean-type climate regions of the world (including the European Mediterranean)
Central Europe	1944	Klika and Hadač (1944)	Annotated checklist of syntaxa of Central Europe
Central Europe	1957	Soó (1957–1963)	Series of papers featuring syntaxa of vegetation of the Pannonian Basin
Central Europe	1963	Ellenberg (1963–1998)	Series of editions of a famous vegetation monograph of Central Europe (1988): English edition; see also Ellenberg and Leuschner (2010)
Central Europe	1967	Hartmann and Jahn (1967)	Account of mountain forest vegetation of Central Europe north of the Alps
Central Europe	1974	Hartmann (1974)	Account of forest vegetation of Central Europe
Eastern Europe	1974	Walter (1974)	A large-scale monograph of vegetation of northern Eurasia, with an account of vegetation of European part of Russia and other states of the former Soviet Union
SE Europe	1974	Horvat <i>et al.</i> (1974)	Detailed account of vegetation of SE Europe and the Balkans
Alps	1983	Ozenda (1983)	Vegetation map of the Alps
Central Europe	1986	von Hübschman (1986)	Survey of European cryptogamic syntaxa
Western Europe	1994	Ozenda (1994)	Account of vegetation of Europe (with emphasize on Western Europe)
Alps	1995	Theurillat <i>et al.</i> (1995)	Survey of high-rank syntaxa of the Alps
Northern Europe	1996	Dierßen (1996)	Detailed authoritative account of the vegetation of northern Europe
Mediterranean	1998	Rivas-Martínez <i>et al.</i> (1998)	List of syntaxa of Spain (including Canary Islands) and the continental Portugal
Mediterranean	1998	Rivas-Martínez <i>et al.</i> (1998–2002)	Series of papers featuring syntaxa of vegetation of the Iberian Peninsula, Balearic Islands and Canary Islands; also available on a website
Europe	2000	Ozenda and Borel (2000)	Ecological map of Europe in paper describing the mapping rationale
Central Europe	2001	Pott (2001)	Account of ecosystems and vegetation of Central Europe

vegetation maps. The consistent conceptual approach of the zonality/azonality approach applied by the Map facilitated a definition of the zonobiomes of Europe in great detail (Figure 1).

The European Vegetation Map has not been the last word in vegetation mapping in Europe. More fine scale projects were conceived and slowly chip away in several countries (e.g., in Czech Republic, Catalonia, Slovenia; see Table 5). An international team of the Circumpolar Arctic Vegetation Map produced goods in 2003 and mapped the vegetation of the Arctic tundra in Eurasia and North America. A team of Circumboreal Vegetation Map (see <http://www.iavs.org>) is underway to write a new article of the Nordic vegetation mapping.

Diversity of Habitat Types

Although vegetation forms, at least in the terrestrial ecosystems, the major component of these ecosystems, the habitat typology cannot and does not reflect only vegetation typology. For instance, as found by Rodwell *et al.* (1998), 60% of the EUNIS3 habitat classification were characterized in phytosociological (syntaxonomic) terms, whereas the other units are largely abiotic and carry geomorphologic and hydrological features or they are associated with fauna or nonvascular plants.

The judgment on the diversity of habitats appears more difficult than that based on the classification of vegetation. First, there are many incommensurable variables to be considered by the definition of a habitat type. Second, the spatial and temporal scaling of the habitat types is very complex. This complexity is reflected in all habitats with habitat complexes recognizable on the classification systems of habitats know until today. To cope with the complexity, the habitat classification systems are hierarchical, but often on the same level of hierarchy, thus mixing small-scale habitats with habitat complexes recognizable on the landscape level. Obviously, the

calibration of the habitat units and the classification system leaves much room for improvement (Rodwell *et al.*, 2002).

Outlook

In Europe, as elsewhere, taxonomic diversity is the leading topic of biodiversity research and conservation. Yet, because of deeply rooted research traditions and the awareness of national governments, surveys on higher levels of biological complexity received considerable attention in the past.

Almost every European nation has national vegetation or land-use maps. Almost all European countries have developed at least a checklist of ecosystems, habitats, or vegetation types and detailed national vegetation surveys have been recently completed or are under way in many crucial European countries (see Tables 4 and 5). The surveys of biotic communities, ecosystems, landscapes, and biomes have been recognized as important tools of both biodiversity conservation and sustainable use of natural resources. With Europe growing together as a union of nations sharing political agendas and an economic future, these tools are becoming standardized, more sophisticated, and effective. Pan-European habitat classification scheme EUNIS3, Habitat Directive of the European Union, vegetation map of Europe (Bohn *et al.*, 2000–2004), unified checklist of the syntaxonomic terminology, and building of standardized vegetation databases (Schaminée *et al.*, 2009) are a few prominent examples. Technology-driven progress in the data handling, GIS-assisted vegetation mapping using automatic data collection (remote-sensing), and analysis is boosting the development of the standardized vegetation and ecosystem survey.

The fall of the Iron Curtain in 1989 and 1990 posed a new challenge for research agendas in ecosystem diversity – unification of scientific standards and application tools along the West–East gradient within Europe. The European Vegetation

Figure 1 Biome maps of Europe derived from the interactive CD-ROM featuring the Map of the Natural Vegetation of Europe (Bohn *et al.*, 2000–2004) using the following key: (a) Polar Desert & Tundra biomes (Units A and B as defined and described in Bohn *et al.* (2000–2004)); (b): Boreal Forest biome (Units C1–2, D1–4, D5.1–5.2); (c) Temperate Deciduous Forest biome (Units D3, D5.3, F, G, K, L; hemiboreal forests units and the montane needle-wood forests of the Alps, Carpathians, and the Caucasus are included as well); (d): Mediterranean biome (Units J); (e) Steppe biome (Units M); and (f) Continental Desert biome (Unit D). The azonal vegetation (P, R, S, T, and U) are not shown. The color codes follow strictly those of Bohn *et al.* (2000–2004).

Table 5 Major vegetation-mapping sources published on and after 2000

Year	Source	Region	Comment
2000	Bohn <i>et al.</i> (2000–2004)	Europe	First comprehensive vegetation map of Europe (2000: legend, 2003: text and maps, 2004: interactive CD)
2001	Ozenda and Borel (2000)	Europe	Ecological map of Europe in paper describing the mapping rationale

Glossary

Benthos Nonplanktonic animals associated with substrata within sediments or closely above the sediment–water interface.

Detritus Nonliving organic matter in both soluble and particulate forms.

Littoral zone Region of a lake or river between the land and the open water (pelagic zone) that is colonized by emergent, floating-leaved, and submersed aquatic plants and their attendant sessile microbiota (periphyton).

Pelagic zone Open-water portion of a lake or reservoir beyond the littoral zone.

Periphyton Bacteria, fungi, algae, and sessile microfauna growing attached to substrata (sediments, rock, plants, animals, sand).

Phytoplankton Small photosynthetic plankton, largely algae and cyanobacteria.

Plankton Small organisms with no or limited powers of locomotion that are suspended in the water and largely dispersed by turbulence and other water movements.

Production Amount of new organic biomass formed over a period of time, and includes any losses from respiration, excretion, secretion, injury, death, and predation.

Zooplankton Small animal plankton, usually denser than water, that sink by gravity to greater depths.

Fresh Waters: Physical Ecosystem Structure

Most water on the Earth's surface is saline in oceans (97.61%), and most of the remainder is polar ice (2.08%) and ground water (0.29%). The remaining water (only 0.009%) exists in freshwater ecosystems as temporary storage in lakes and reservoirs on land. These surface waters have much shorter renewal times than those of the oceans (Table 1). The volume of water flowing from these storage sites to the sea in streams and rivers is very small (0.00009% of total water), with a mean residence time of about two weeks. During high-precipitation periods, surface waters of rivers increase and often recharge adjacent groundwater aquifers. Return flows from ground water to rivers occur during periods of low flow or drought, and usually maintain a base flow in river channels.

The storage of water in lakes and retention times are altered by shifts in the balance between inputs from all sources and water losses. Lakes receive water from precipitation directly on the surface, from surface inflows from the drainage basin, and from subsurface groundwater seepage. Lakes lose water by flow from a usually single outlet (*drainage lakes*), by seepage through the basin walls into the ground water (*seepage lakes*), evaporation, and evapotranspiration from higher aquatic plants. Saline lakes, which constitute nearly half of inland surface waters (see Table 1), occur in *closed* basins with no outflow except by evaporation. That evaporation results in a gradual marked increase in residual concentration of dissolved salts that were imported with influent water.

Natural lakes are concentrated in the subarctic and temperate regions of the Northern Hemisphere, whereas reservoirs are constructed predominately in the subtemperate and subtropical regions. Some 40% of the total volume of surface freshwater is contained in seven great lake basins of Siberia (Lake Baikal), North America (the Laurentian Great Lakes: Superior, Michigan, Huron, Erie, and Ontario), and eastern Africa (Lake

Tanganyika). Most of the millions of lakes and reservoirs, however, are very much smaller and relatively shallow, usually <15 m in depth (Figure 1). Mean depths are even more shallow (<5 m). As a result, light commonly penetrates to over half of the sediments within the basins of a large percentage of lakes. Photosynthesis can thus occur not only by algae that are suspended in the water column but can extend to higher aquatic plants and attached algae. Major flowing-water ecosystems occur in low-gradient tropical and subtropical regions and are posited to support high photosynthetic productivity in extensive floodplain and land–water interface regions.

The productivity and internal metabolism of aquatic ecosystems are driven and controlled by energy from solar radiation acquired by photosynthesis. Inland waters receive organic products of photosynthesis directly from their aquatic flora and indirectly from their drainage basins as particulate and dissolved organic matter from terrestrial and wetland plants imported by stream water, storm runoff, ground water, and the atmosphere.

Light is attenuated exponentially with increasing depth in water. As the light is attenuated, ultraviolet wavelengths are absorbed strongly by dissolved organic compounds in the water. The blue portion (500–600 nm) of the visible spectrum penetrates most deeply in relatively clear waters. Infrared wavelengths are absorbed rapidly, largely as a result of the molecular structure of water molecules, and much of this energy is dissipated as heat. Because water becomes less dense as heat content increases above 4 °C, the less dense warmer water floats upon the more dense cooler water. This density stratification results in separation of major strata within lakes, where a warmer, less dense stratum (*epilimnion*) overlies a cooler, denser zone (*hypolimnion*). The interface zone (*metalimnion*) is a region of rapid thermal discontinuity, often as much as several degrees change per meter, between the epilimnion and the hypolimnion.

Table 1 Water in the biosphere^a

	Volume (thousands of km ³)	Percentage of total	Renewal time
Oceans	1,370,000	97.61	3100 years ^b
Polar ice, glaciers	29,000	2.08	16,000 years
Groundwater (actively exchanged) ^c	4000	0.295	300 years
Freshwater lakes	125	0.009	1–100 years ^d
Saline lakes	104	0.008	10–1000 years ^d
Soil and subsoil moisture	67	0.005	280 days
Rivers	1.2	0.00009	12–20 days ^e
Atmospheric water vapor	14	0.0009	9 days

^aWetzel (1983, 2000). Slightly different values are given by I. A. Shiklomanov, but ratios are similar.

^bBased on net evaporation from the oceans.

^cKalinin and Bykov estimated that the total groundwater to a depth of 5 km in the earth's crust amounts to 60×10^6 km³. This is much greater than the estimate by the U.S. Geological Survey of 8.3×10^6 km³ to a depth of 4 km. Only the volume of the upper, actively exchanged groundwater is included here.

^dRenewal times for lakes vary directly with volume and mean depth, and inversely with rate of discharge. The absolute range for saline lakes is from days to thousands of years.

^eTwelve days for rivers with relatively small catchment areas of less than 100,000 km²; 20 days for major rivers that drain directly to the sea.

Figure 1 Approximate number of lakes of the world in relation to lake area and approximate mean water depth. (Wetzel (1990)).

The resulting density stratification affects not only the thermal structure and water mass stratification, but also the hydrodynamics of lakes and reservoirs. Heat is distributed and altered by the physical work of wind energy, currents and other water movements, basin morphometry, and water losses. Patterns of density-induced stratification influence physical and chemical properties and cycles both spatially within the lake and seasonally. These characteristics structure the aquatic habitats and have marked attendant effects on all chemical cycles, metabolic rates, and the population dynamics of organisms and their productivities.

The total *salinity* of inland waters nearly always consists of eight most abundant ionic species, of usually four major cations (Ca^{2+} , Mg^{2+} , Na^{+} , K^{+}) and four anions (HCO_3^{-} , CO_3^{2-} , SO_4^{2-} , Cl^{-}). The salinity of fresh waters has a

world average concentration of about 120 mg/L, but varies among continents and with the lithology of landmasses (Table 2).

Of the major constituents of the cellular protoplasm of organisms (C, H, O, N, P, and S), the biogeochemical cycles control the physical and metabolic availability of phosphorus, nitrogen, and several minor nutrients. These elements often limit biotic development, particularly photosynthetic generation of organic matter. Phosphorus, in comparison to other macronutrients required by biota, is least abundant geochemically in a large portion of the global landforms and drainage. As a result, phosphorus is commonly the first element to limit biological productivity, especially of photosynthetic producers and heterotrophic microbiota. When phosphorus is in adequate supply, nitrogen availability

Table 2 Mean composition of river waters of the world (mg L⁻¹)^a

	Ca ²⁺	Mg ²⁺	Na ⁺	K ⁺	CO ₃ ²⁻ (HCO ₃ ⁻)	SO ₄ ²⁻	Cl ⁻	NO ₃ ⁻	Fe (as Fe ₂ O ₃)	SiO ₂	Total

invariably limits productivity. Standing inland waters have been categorized into various trophic scales on the basis of ranges of major nutrients and algal productivity (Table 3).

Functionally similar organisms of biological communities can be grouped into *trophic levels* based on similarities in patterns of organic matter production and consumption. Energy is transferred and nutrients are cycled within an overall ecosystem trophic structure. The productivity of each trophic level is the rate at which energy enters the trophic level from the next lower level. Because organisms expend considerable energy for maintenance and since death of an organism routes much energy and nutrients into the detrital pool of dead organic matter, only a portion of the energy of one trophic level is available for transfer and use by higher trophic levels. Available energy decreases progressively at higher trophic levels, so that rarely can more than five or six trophic levels be supported. The efficiency of energy transfer from one level to the next is low (5–15%), and often decreases as trophic level increases.

The organic matter of freshwater ecosystems is primarily (>90%) dead organic matter, and most (usually 80–90%) of this organic detritus occurs as soluble or colloidal organic compounds. Oxygen, however, is very insoluble in water, and most diffuses to the atmosphere. When organic matter in lakes is metabolized and organic compounds respired by heterotrophic organisms, the amount of organic matter to be oxidized can be much larger than the dissolved oxygen available for oxidation. This limitation can become acute when lakes are stratified by density differences, and exposure of deep strata to oxygen of the atmosphere may be restricted for long periods of time (months).

In large lakes, the volume of water with sufficient light to support photosynthesis (*euphotic zone*) is small relative to the total volume of water containing stored dissolved oxygen that can be used in heterotrophic respiration. In small and relatively shallow lakes, however, the proportion of water supporting photosynthesis is large relative to total lake volume, and respiratory demands can exhaust oxygen dissolved in the lower strata of the lake. The process of eutrophication exacerbates the exhaustion of dissolved oxygen in large portions of lake ecosystems. *Eutrophication* is the increased loading of organic matter to an aquatic ecosystem. Often in lakes, eutrophication results from increased photosynthetic production

of organic matter in response to excessive loading of nutrients, particularly phosphorus, to the water from external sources.

When dissolved oxygen is depleted from water strata, alternate electron acceptors are utilized by microbial metabolism of dissolved organic compounds. Bacterial denitrification occurs by biochemical reduction of oxidized nitrogen anions (NO₃⁻ and NO₂⁻), concomitant with the oxidation of organic matter by many genera of facultative anaerobic bacteria. When nitrate and nitrite are depleted, alternative oxidized ions can function as electron acceptors, although with decreasing efficiencies—manganese, iron, and particularly sulfate, the latter being reduced to hydrogen sulfide. Often the same compound can serve as a hydrogen acceptor or donor, depending on the environmental conditions. When these electron acceptors are essentially depleted, organic matter can be anaerobically degraded by fermentation to methane and CO₂ in two stages. Facultative and obligate anaerobic bacteria convert proteins, carbohydrates, and fats primarily to fatty acids by hydrolysis and fermentation. Obligatory anaerobic methanogenic bacteria then convert the organic acids to methane and CO₂.

Diversity of Habitats

Freshwater ecosystems consist of entire drainage basins as water moves from land and in groundwater runoff to stream and river channels, and to recipient lakes or reservoirs. The nutrient and organic matter content of drainage water from the catchment area is modified in each of the terrestrial soil, stream, and wetland–littoral components as water moves downgradient to and within the lake or reservoir itself (Figure 2). Photosynthetic productivity of organic matter is generally low to intermediate in the terrestrial components, highest in the wetland–littoral interface regions between the land and water, and lowest in the open water (*pelagic*) zone. The same productivity profile emerges in the gradient from land to river channels, where the greatest productivity occurs in the marginal floodplain regions. Autotrophic productivity in river channels is generally low, as is also the case in the pelagic regions of lakes. Most of the organic matter utilized by heterotrophic communities in running water is imported from floodplain and terrestrial sources as particulate and especially dissolved and colloidal organic compounds.

^bReferring to approximately net primary productivity, such as measured by the ¹⁴C method.

Figure 2 The lake ecosystem showing the drainage basin with terrestrial photosynthesis (PS) of organic matter, movement of nutrients and dissolved (DOM) and particulate (POM) organic matter in surface water and groundwater flows toward the lake basin, and chemical and biotic alteration of these materials en route, particularly as they pass through the highly productive and metabolically active wetland-littoral zone of the lake per se (net organic productivity in metric tons per hectare per year). (Wetzel (1990)).

The interface region between the land and water is always the most productive per unit area along the gradient from land to the open water of lakes, reservoirs, and streams. Because most aquatic ecosystems occur in geomorphologically mature terrain of gentle slopes and are small and shallow, the wetland-littoral components usually dominate in both productivity and the synthesis and loading of organic matter to the systems. The region of greatest productivity is the emergent macrophyte zone. Emergent aquatic plants have a number of structural and physiological adaptations that not only tolerate the hostile reducing anaerobic conditions of saturated sediments but also exploit the high nutrient conditions and water availability of this habitat. Nutrients entering the zone of emergent macrophytes from external sources tend to be assimilated by bacterial and algal microflora of the sediments and detrital organic particles, and are then recycled to the emergent macrophytes. Dissolved organic compounds released from decomposition of plant detrital materials dominate the export of organic matter from the emergent plant zone.

Submersed macrophytes are limited physiologically by slow rates of diffusion of gases and nutrients in water within the boundary layers surrounding the leaves and by reduced availability of light underwater. Internal recycling of resources, particularly of gases (CO_2 , O_2) of metabolism and of critical nutrients, is important to the abilities of submersed

plants to function and grow as well as they do in underwater conditions of chronic light and gas limitations. Despite these adaptive mechanisms, growth and productivity of submersed plants are less than those of emergent and floating macrophytes.

The second most productive component of the wetland-littoral community is the microflora attached to aquatic plants epiphytically and to other surfaces, both living and dead. The surfaces provided by aquatic plants in lakes and rivers can be very large, often exceeding 25 m² per square meter of bottom sediments. High sustained growth of attached microflora results from their recycling of essential gases (CO_2 , O_2) and dissolved nutrients within the attached communities. Nutrient uptake from the surrounding water is directed primarily to the high net growth of attached microflora and is responsible for the high capacity of wetland-littoral areas to improve the quality of water passing through these communities.

The wetland-littoral complex of higher plant and microbial communities produces the major sources of organic matter and energy of many freshwater ecosystems, including the marginal floodplains of many rivers. Most of the particulate organic matter is decomposed within these interface regions. Organic matter is exported predominantly from these marginal regions as dissolved organic matter to the recipient lake or river (Figure 3).

Figure 3 Lateral and vertical boundaries of flowing-water ecosystems. The stream ecosystem boundary is defined as the hyporheic/groundwater interface and thereby includes a substantial volume beneath and lateral to the main channel. Vegetation rooted in the hyporheic zone is therefore part of stream ecosystem production. Arrows indicate flow pathways of dissolved organic matter and inorganic solutes derived from plant detritus within the stream ecosystem. (Reproduced from Wetzel RG and Ward AK (1992) Primary production. In: Calow P and Petts GE (eds.) *Rivers Handbook*, pp. 354–369. Oxford: Blackwell Scientific, UK, with permission from Wiley.)

The deep-water pelagic zone of lakes is the least productive along the gradient from land to water (see Figure 2), regardless of nutrient availability. Growth of phytoplanktonic algae of the pelagic zone is limited by sparse distribution in a dilute environment where efficient nutrient recycling is restricted by the sinking of senescent phytoplankton below the depth of photosynthesis. When nutrient recycling and availability are increased, greater phytoplankton cell densities attenuate underwater light and reduce the volume of water in which photosynthesis occurs. Despite low productivity per unit area, pelagic productivity can be collectively important in large lakes and for higher trophic levels that depend on this source of organic matter.

Higher trophic levels of communities in freshwater ecosystems consist of zooplankton (dominated by four major groups of animals: protozoa/protista, rotifers, and the crustaceans cladocera and copepoda) and benthic invertebrates. In the pelagic zone, small fishes, fry of larger fishes, and predatory zooplankton, which collectively comprise a third trophic level (primary carnivores), consume a portion of these generally herbivorous organisms. A fourth trophic level may consist of medium-sized piscivorous fishes, and the fifth level of large predatory piscivorous fishes. Higher trophic levels are rare in freshwater ecosystems.

The species composition of the higher trophic levels affects the pathways of energy utilization from lower trophic levels. Environmental factors that selectively influence the populations of the communities can alter the pathways and strengths of energy fluxes from subordinate trophic levels. For example, efficiency of consumption of primary production by zooplankton is often appreciably greater in the absence of zooplankton-feeding fishes than in their presence. The population structure of the phytoplankton community responds variably to grazing impacts in concert with their available resources (light, nutrients, and organic constituents). The phytoplankton community may or may not be able to compensate for grazing losses in overall primary production, but generally is able to shift quite quickly to an alternative, less vulnerable species composition.

Ecosystem Functions: Interactive Regulatory Mechanisms

Most of the organic carbon of aquatic ecosystems, and hence much of the energy potentially available for metabolism of heterotrophic biota of the ecosystem, exists as dead organic matter (*detritus*), in both dissolved and particulate forms. Dissolved organic matter and much of the particulate organic matter, usually expressed as organic carbon, move with the water. Much of the particulate organic matter that is not decomposed ultimately settles by gravity and is deposited at the bottom of static water bodies. Dissolved organic compounds can also sediment if adsorbed to inorganic or organic particulate matter or if polymerization and aggregation occur into particulate form. Because much of the highest photosynthetic production of organic matter occurs in shallow regions of lakes and streams, and because most lakes are small and shallow, most heterotrophic decomposition occurs in benthic regions as organic matter. Therefore, because much of the organic matter is displaced to the sediments, most of the total heterotrophic decomposition is also largely displaced from sites of production to the sediments.

The specific composition of organic matter varies greatly. The organic matter of pelagic phytoplankton, which can dominate in-lake production in very large, deep lakes, is relatively labile. Much of the phytoplanktonic algal and cyanobacterial organic matter is decomposed by microbiota either in the water column within the water strata of production or below as it sediments to the bottom. Some highly variable portion, usually much less than 50% on an annual basis, of the phytoplanktonic organic matter is ingested and partially digested by zooplankton. An appreciable portion, usually >50%, of that particulate organic matter ingested by zooplankton is egested as dissolved and as particulate organic matter, some of which also settles as feces to the sediments.

The composition of organic matter of the wetland and littoral regions of lakes and streams tends to be considerably more recalcitrant to rapid microbial degradation than that of

phytoplankton because of the littoral dominance of lignocellulose-based organic compounds of structural tissues of higher plants. Because of the much higher rates of production and slower rates of decomposition of both the particulate and dissolved organic matter from these shallow-water sources, and because of the shorter distances and times for particulate organic matter to be displaced to the sediments, organic matter accumulates on and in the sediments at greater rates in shallow regions than in those of the pelagic region. The deposition of organic matter in the sediments encourages intensive bacterial metabolism. As a result, intrusion of dissolved oxygen from the overlying water is consumed rapidly; nearly all sediments in standing freshwater ecosystems are anaerobic and highly reducing chemically.

Although the specific composition of organic matter varies greatly, detritus inevitably carries most of the energy of the ecosystem from its points of photosynthetic origins to places of transformation by heterotrophic organisms. Most of that heterotrophic transformation occurs by microbes in areas where organic matter is concentrated. Even though greater than 70% of the very large pool of dissolved organic matter of the pelagic region of lakes and rivers consists of relatively recalcitrant humic and fulvic acids that originated from higher plants, these compounds are slowly metabolized by bacteria, often being catalyzed by partial photolytic degradation by ultraviolet light (both UV-A and UV-B). In contrast, much of the particulate organic matter of the productive littoral areas accumulates on the bottom, largely under anaerobic conditions particularly in sediments and in detrital mats.

Transformation of particulate organic matter of the pelagic zone also occurs by digestion in predatory metazoan animals as well as by pelagic microbes. Productivity of the microbes is maximized within the resources available from dead organic matter and nutrients. Microbial heterotrophic utilization is highly dynamic and changes with sufficient rapidity to allow many generation turnovers before predators with much slower turnover rates can respond reproductively to changes in availability. Viral mortality of microbes, as well as ingestion of bacteria by protists (the "microbial loop"), diverts much organic matter from animal trophic levels. Bacterial, viral, and much of protistan heterotrophic metabolism as respiration represents a major output of carbon, largely as CO_2 , from the aquatic ecosystem. Although this output is a loss of carbon from the ecosystem, it is not an energetic loss from the ecosystem.

That productivity that is not ingested by metazoan animals is of major importance and dominates the energy flows within the pelagic region. Nonpredatory death and metabolism by prokaryotic and protistan heterotrophs usually dominate energy flows within the pelagic region and completely dominate energy flows of the composite wetland-littoral, benthic, and pelagic components that collectively constitute freshwater ecosystems. Even ignoring the benthic portions of lakes where most of the organic carbon metabolism occurs and considering only the pelagic metabolism of lakes, for example, most of the organic carbon entering the system does not reach higher trophic levels.

The microbial heterotrophy is of primary importance to higher trophic levels by means of feedback processes, both positively (e.g., nutrient recycling and utilization by primary producers) and negatively (e.g., oxygen consumption and

production of toxic fermentative metabolic end products). The abundance, distribution, and microbial decomposition of dissolved and particulate detritus both regulate and stabilize energy metabolism and nutrient availability in aquatic ecosystems. Because of the very large magnitudes and relative chemical recalcitrance of these detrital sources, the large but slow metabolism of detritus provides an inherent ecosystem stability that energetically dampens the ephemeral, volatile fluctuations of numbers and biomass of the biota of higher trophic levels.

Biodiversity Within Freshwater Ecosystems

The biodiversity of most microbial, plant, and animal groups of freshwater stream, lake, and wetland ecosystems is very poorly known on a global basis. Moreover, it is likely erroneous to believe that biodiversity of many taxa in temperate ecosystems is appreciably less than that in tropical freshwater ecosystems. For example, the rivers and streams of Alabama, a "hot spot" within the United States, contain 43% of all gill-breathing snails, 52% of freshwater aquatic or semiaquatic turtles, 60% of mussels, and 38% of freshwater fishes of North America (Lydeard and Mayden, 1995). Over half of the species in some of the groups mentioned are either threatened or endangered under the U.S. Endangered Species Act of 1973.

The fresh waters of the world are collectively experiencing markedly accelerating rates of degradation. Major sources of disturbance impact the biodiversity of freshwaters in many ways. Direct chemical toxicants released into surface waters and ground waters are common. Many forms of heavy metals, inorganic reducing agents, and organic compounds enter the environment and eventually fresh waters. Although some are inactivated, such as by chemical precipitation, or oxidized, many have long residue resident times. Despite dispersion and dilution in the aquatic environment, bioconcentration of both metals and organic compounds is common, by which toxicity can be increased exponentially. The biological effects of many of these compounds are unknown. Elemental and compound toxicity is increased markedly when the pollutant substances are radioactive or acidic. Increased acidity in poorly buffered fresh waters can increase concentrations and potential biotic availability and toxicity of metals, such as aluminum, that are not normally abundant in soluble, reactive states.

Nutrients, particularly phosphorus and nitrogen, can lead to well-understood enhancements of plant and other organic productivity in fresh waters. This eutrophication process often results in enhanced rates of decomposition and in chemical conditions that greatly reduce or eliminate suitable habitat for many species of plants and animals. Similar excessive loading of organic matter and enhanced rates of degradation result from organic sewage from human populations, industry, and agriculture. A further common pollutant that markedly reduces habitat availability is the suspension of finely divided organic and inert inorganic matter. Erosion and transport of such suspensions are increasing as large areas of forest and former wetland interface zones between land and water are eliminated, primarily for agricultural expansion. As a result, flow patterns of surface waters are often altered and benthic habitats of surface waters can be obliterated by sedimentation.

Changes in biodiversity in freshwater ecosystems can arise from many other disturbances. Introduction of certain competitively superior species can result in marked losses of biodiversity. The infamous example of introduction of the Nile perch into Lake Victoria of East Africa resulted in the extinction of over 200 species of its endemic cichlid fish taxa in two decades. There are many other examples of introductions of exotic plant and animal species that resulted in either direct destruction of prey or inferiorly competitive species or indirect alteration of habitats required by many species. Dense, floating macrophyte communities and other eutrophication-associated excessive plant productivity often result in deoxygenation and reduction in habitat and elimination of many plant and animal species.

Largely based on terrestrial studies, the Eltonian diversity–stability hypothesis suggested that, because of the many different traits of multiple species, ecosystems with more diverse habitats would likely have species that will survive and expand during and following an environmental disturbance and compensate for those species that are reduced by the disturbance. Therefore, a more species diverse freshwater ecosystem should be more resilient to disturbances than a less biodiverse system.

Because genetically based physiological differences and tolerances among species can be small, the individual interactive strengths of some species in a freshwater ecosystem can become saturating at high biodiversity. A point can be reached where increasing species may be functionally redundant and have reduced individual impact on the ecosystem processes. On the basis of both theoretical and experimental grounds, only a small fraction of species manipulations have strong influences on food web structure. Species redundancy implies that an appreciable functional resiliency exists in which the ecosystem can compensate in its collective metabolism and biogeochemical cycling when disturbed. Although the population dynamics become progressively less stable as the biodiversity and the number of competing species increases, biodiversity can enhance the resiliency of many community and ecosystem processes in the rate that the system metabolism returns to equilibrium states following a disturbance.

There is very little storage capacity for organic carbon within the higher trophic levels. Low residence times among the higher trophic levels results in rapid cycling of carbon and nutrients of food web components. Such rapid cycling and recycling result in a reduction in the resiliency of the higher trophic levels. Most of the storage of organic carbon occurs in the dissolved organic carbon compartment in the open water and in the particulate organic carbon deposited in the sediments. In both of these compartments, the soluble organic carbon of the pelagic areas of lakes or running water of streams and the organic carbon of the sediments, the cycling of carbon is slowed. That rate of cycling is slowed in the pelagic by the recalcitrant chemical composition of the dissolved organic carbon emanating largely from higher plants. In the sediments, cycling is further impeded by the anoxic conditions that prevail almost universally among aquatic sediments. The reduced rates of cycling and recycling result in an inherent increase in resilience stability of the ecosystem.

Any factor that influences the rates of nutrient and carbon cycling in freshwater ecosystems will influence the resilience of

the ecosystem and its biodiversity to disturbances. Changing sources of organic matter, as discussed in the following, and hence bacterial metabolism and nutrient cycling thus change resilience and biotic stability.

A wealth of limnological data from a spectrum of hundreds of lake ecosystems of differing productivity suggests that with a shift in nutrient loadings, concomitant shifts occur in the development of photosynthetic producers and loadings of organic matter. During the common sequential development of lake ecosystems over long periods of time (centuries, millennia), shifts in the ratios of higher vegetation versus algal dominance can occur. Increased relative organic loading from higher vegetation results in proportionally greater loading of recalcitrant dissolved organic carbon, which can suppress nutrient cycling and increase the resilience of the ecosystem.

In addition, the development of higher vegetation in littoral and wetland combinations increases the habitat heterogeneity enormously, often by a factor of 10 or more, in comparison to lakes with limited littoral development. Species diversity nearly always increases under these circumstances by at least an order of magnitude among nearly all major groups of organisms, particularly among the lower phyla.

Greater biodiversity may have a greater collective effect by improving the capacity of ecosystems to recover from large disturbances. Reduced biodiversity increases vulnerability by reducing the total collective physiological tolerances of the community to large habitat changes. Recovery after a major or catastrophic disturbance would be slower with a reduced aggregation of residual physiological ranges within the remaining species. Recovery then must depend to a greater extent on slower fortuitous methods, such as importation of species, rather than generation from residual surviving species, or slow recolonization processes such as from remnants in resting stages or seed banks. In some cases, such as in many ponds, streams, and reservoirs in clay-rich regions where high turbidity often occurs with successive rain events, photosynthetic productivity within the water is intermittently but repeatedly suppressed. Biodiversity is likely also suppressed under these conditions or restricted to species with high reproductive potential that utilize improved conditions in periods between turbidity events.

As indicated earlier, disturbance to freshwater ecosystems can occur in many forms and to different extents. Certain perturbations can be catastrophic, such as overwhelming a lake or stream with an organic or inorganic poison in which most of the biota are eliminated. Many disturbances, however, are more gradual over long periods of time (months, year), such as nutrient enrichment, or irregularly episodic and often of short duration (days, weeks), such as severe flooding and the scouring of a section of river. Biodiversity is coupled to ecosystem stability and the type and extent of disturbances.

A model of the responses of organic productivity of lake ecosystems to changes in nutrient loading from the drainage basins has been abundantly verified by nutrient and comparative primary productivity data of phytoplankton, attached algae, and macrophytes from hundreds of lakes in different stages of ontogeny (Figure 4). The differences in plant productivity result in very different amounts and types of chemical composition of organic matter loaded to lakes. Because of the large amounts and relative chemical recalcitrance of dissolved

Figure 4 Relative changes in the primary productivity of phytoplankton, macrophytes, and attached microflora, and habitat diversity, species diversity, and ecosystem stability along a gradient of nutrient loading to lake ecosystems. (Reproduced from Wetzel RG (1999) Biodiversity and shifting energetic stability within freshwater ecosystems. *Arch. Hydrobiol. Beih. Ergebn. Limnol.* 54: 19–32, with permission from Cornell University Press.)

and particulate organic detrital sources from higher plants, decomposition of this pool is slowed. The resulting large but slow metabolism of organic detritus provides an inherent ecosystem stability that energetically buffers the organic matter reserves from rapid exploitation and cycling of nutrients contained in the organic matter. Forested watersheds, undisturbed riparian floodplains, and wetland–littoral zones are therefore important to the metabolic stability within the lakes and streams as a result of both the chemical quality and the large quantity of their inputs of organic matter. The organic carbon couplings between the drainage basin and land–water interface zones are metabolically as important to lake and stream energetic and carbon utilization stability as are the traditionally studied nutrient (phosphorus, nitrogen, silica) loading relationships to food web productivity. As the sources of organic matter change, the chemical recalcitrance to degradation can change. Alterations of rates of utilization, nutrient recycling, and energetic resiliency can ensue as a result. These changes directly affect biodiversity by altering the chemical and physical habitat characteristics.

A common disturbance to lake and reservoir ecosystems involves progressive increases in loading of nutrients. These loadings, in excess of losses to sites of temporary or permanent inactivation such as to the sediments, result in enhanced

nutrient availability for phytoplankton and other autotrophs and increased rates of growth and productivity. If nutrient loading increases to an oligotrophic lake, increased productivity is rapid. Similarly, if the disturbance is brief (i.e., the duration of increased nutrient loading is relatively short), nutrient cycling is rapid, the ecosystem will recover rapidly, and productivity would be reduced proportionally to the load reduction. The return time of such an oligotrophic ecosystem is high, but the resiliency is low. Species diversity of the plankton tends to be high in oligotrophic lakes, but because of limited physical habitats, particularly associated with littoral areas and surfaces, composite biodiversity of the lake ecosystem would be low (see Figure 4).

As nutrient loading increases, particularly among shallow lakes that predominate globally, a marked shift in the productivity occurs from the pelagic to attached surfaces associated with living aquatic plants and the particulate detritus of senescing macrophyte biomass (see Figure 4). Under these conditions, total primary productivity and biomass increase greatly. Habitat diversity among the massively dissected surfaces of submersed aquatic plants increases exponentially, and biodiversity among attached biota would increase by at least an order of magnitude. It is likely that among all autotrophic and heterotrophic microbial groups, as well as for most of the smaller metazoans, over 90% of the total freshwater ecosystem species are sessile in association with surfaces.

As nutrient loading increases further, phytoplanktonic productivity per unit volume increases, but self-shading by the suspended algae restricts the depth of light penetration and hence the depth of the photogenic zone. Phytoplanktonic productivity per unit area declines precipitously under these eutrophic conditions of light limitation and is usually accompanied by a marked decrease in planktonic biodiversity as well (see Figure 4). Submersed light limitations also reduce or eliminate submersed macrophyte growth and attendant surfaces for microbial growth. The elimination of photosynthesis of attached microbiota decreases collective productivity markedly. Biodiversity of the attached biota would decline precipitously as a result. The losses of attached microbial communities and their interdependent metabolism cause a massive reduction in the capacities of the lake ecosystems to retain loaded nutrients and dissolved organic compounds. Because of the great accumulation and recycling of nutrients in the sediments from a predominantly planktonic eutrophic ecosystem, the time for recovery of the water quality of a lake from a reduction of nutrient loading would be long and not proportional to load reductions. Under these conditions after the nutrient loading perturbations end, the internal nutrient loading and recycling could be greater than external nutrient loading.

Continual high nutrient loading and resulting hypereutrophic phytoplanktonic conditions generate large areas of anaerobic reducing conditions and slower rates of decomposition of organic matter. Production exceeding decomposition leads to rapid sedimentation and generation of increased shallow habitat conducive to colonization by emergent macrophytes. The high productivity of emergent macrophytes increases the proportion of lignocellulose supporting tissues that are relatively recalcitrant to rapid decomposition, particularly under reducing conditions. The collective result is markedly increased productivity and habitat

diversity. However, although habitat diversity is high among very shallow wetland-dominated waters, environmental fluctuations are also more extreme than in continually submersed habitats. Quite different community structures occur and biodiversity is likely tempered as a result, though comparative data to support this statement are few.

Many descriptive and experimental studies suggest that greater biodiversity results in a higher efficiency of utilization of nutrients. Greater biodiversity likely entails more physiological diversity that can better cope with natural vagaries in environmental parameters. Competition for resources, nutrients in this specific case, is thus intensified. Efficiency of nutrient retention in an ecosystem would be maximized under conditions of greatest microbial community diversity. That microbial diversity (algae, fungi, protists, and bacteria) is maximized in the attached communities where habitat diversity and microenvironment differences are the greatest. Physical constraints of boundary layers and mucopolysaccharide matrices in which the attached microbiota live mean that movements of ions and gases to organisms living within the attached communities occur predominantly by diffusion. Nutrients, once acquired, are intensively recycled among the attached biota and conserved. Resources from external sources can then be utilized largely for new growth and reproduction. Nutrient retention is very high within the micro-communities and collectively within the attached habitats.

In certain productive lakes, piscivore consumption of planktivorous fishes can lead to enhanced development of cladoceran zooplankton. The high grazing rates of cladoceran zooplankton can result in selective reduction of larger algae for brief to moderate intervals of time. The effects of these changes among the larger forms are, however, poorly translated to smaller microbiota, and only minor changes are seen at the microalgal and bacterial levels. For example, removal of portions of the larger algae can decrease competition for nutrient and light resources. Often the smaller forms with shorter generation times increase in productivity. Nutrient recycling likely also increases, particularly as decomposition of

these algae by bacteria is accelerated by protistan micro-consumers (heteroflagellates, ciliates, and related organisms) and tightly retained among the microbiota. Little is known concerning changes in biodiversity under these conditions, but it appears that biodiversity among the microbiota would increase and likely compensate for the losses of larger forms by the crustacean grazing. A shift in energy fluxes occurs, here from larger planktonic forms to smaller forms with much higher turnover rates and increased rates of resource turnover. Compensatory mechanisms likely also appear in the composite biodiversity of the smaller biota. Resiliency to disturbances within the pelagic food web likely declines as a result.

Glossary

Detritus Dead organic matter.

Denitrification Bacterial nitrate respiration of organic matter to elemental nitrogen under oxygen-free conditions in soils and aquatic sediments.

Oxic and anoxic conditions Environmental conditions with and without oxygen, respectively.

Red lists Compilations of recently extinct, threatened, and vulnerable species for a country or a larger region.

Secchi depth Measurement of the transparency of water by determining the depth at which a white Secchi disk (diameter 20 cm) lowered from the surface disappears out of the sight of the observer.

Freshwaters: Opportunities and Conflicts

Why are humans so interested in freshwater and natural freshwater ecosystems? The answer is obvious – humans cannot live without it! Freshwater is an essential resource for daily life and for the production of vital food and industrial products.

Freshwater is used for drinking and for cooking. It is also used for bathing, washing clothes, and removing waste products. Securing clean tap water and good sanitary conditions through installation of water closets and sewer pipelines has been important in reducing infectious diseases and infant mortality. In their daily lives, people also enjoy natural lakes and streams, which provide variation in the landscape and opportunities for bathing, fishing, sailing, and observing animal and plant life. Therefore, for human beings, the availability of clean and uncontaminated freshwater habitats in large numbers should be of high priority.

Freshwater is also required for irrigation, in many industrial processes, and for the transportation of waste products. Because of the magnitude of these uses, the pressure on groundwater and surface water is immense in regions with dense populations and intense agriculture and industry. Unfortunately, many of the uses deteriorate water quality, thereby affecting water use for other purposes. The growing number of uses and users generates conflicts among neighboring countries and different user interests, and further exacerbates the dilemma of rising demand and the need and desire for high-quality aquatic habitats. Overall, freshwater ecosystems have been more restricted, manipulated, and polluted than any other ecosystem on Earth, and conflicts will intensify in the future in the light of growing human populations and contemporary environmental trends.

The Small, but Numerous Freshwater Habitats

Earth has much water. A deep, continuous ocean covers 70% of Earth's surface and contains 97% of all water. Only 0.65% of all water is found as freshwater on the continents, and most of this is groundwater (0.62%). Even smaller proportions are found in streams (0.0001%) and lakes (0.017%).

Lakes and streams cover a variable proportion of the land surface. In dry regions, surface waters cover less than 0.1% of the land surface. In wet environments such as the tundra, the boreal forest, and the rainforest, plenty of water is found in shallow pools, lakes, and streams, which may occupy 5–10% of the land surface. A map of Great Britain reveals that surface waters cover less than 0.1% of the land in the south and more than 5% in the rainy uplands of Wales and northwest Scotland; the average water coverage is 1–2%.

Because inland waters are mostly small, shallow, and numerous, they form an intimate contact with the terrestrial environment. This contact has been essential for the historic and contemporary development of species and life stages of amphibious plants and animals. Despite the small volume of lakes and streams compared to the ocean's volume, freshwater environments have been a vital platform for the evolution of many lines of algae, plants, and animals.

It is possible to quantify the contact between terrestrial and freshwater environments. In a small country like Denmark, inland waters occupy 1.7% of the terrestrial area, and on average, 1 km² of land area is in contact with 3.6 km shoreline of freshwater lakes and streams and 0.2 km of the sea. Before agriculture removed numerous shallow lakes, pools, and streams, the freshwater contact was 2–3 times longer.

The greater land contact to freshwaters than to the sea is even more striking for the world, because land areas are joined in large continents. As land masses grow in size, the contact zone to the sea increases only with the periphery and, thus, with the square root of the land area, whereas the contact zone with inland waters approximately increases in proportion to the land area. For the continents, the estimated contact zone is 100–1000 times longer between land and freshwater than between land and sea.

The transition between land and freshwater is gradual, gentle, and suitable for organisms, because physical forces and disturbance are weaker than in the transition from land to sea. The transition zone from small lakes and streams to land has a closed vegetation cover; that of the oceanic coasts faces strong winds, waves, and moving sand with only scattered vegetation. It has been much easier for organisms to cross between land and freshwaters than between land and the sea. The many new freshwater bodies that are formed during glaciations or appear transiently during wet periods also offer opportunities for the

emigration and development of new species without the intense competition and predation caused by well-established species, as is typical of the sea. In contrast, shallow lakes disappear after only a few thousand years, because they are filled with particles eroded from the land and organic matter produced in the lake. In essence, freshwaters provide many opportunities, which constantly come and go, but individual lakes lack the long-term stability of the sea that has lasted for billions of years.

This scenario should have stimulated the selection of species with rapid evolution and efficient means of dispersal allowing them to colonize new freshwaters as their original habitats disappear. Indeed, apart from species of fish, molluscs, and crustaceans associated mainly with large ancient lakes (e.g., Lakes Baikal, Titicaca, and Victoria) and large ancient river systems (e.g., the Danube, Amazonas, and other tropical rivers), most freshwater species are widespread within and even among continents. Freshwater microorganisms among the bacteria, algae, and protozoans are generally both locally abundant and cosmopolitan. Most aquatic rooted plants are also widespread, though a few species are endemic because underwater dispersal restricts their spread.

Species Evolution and Richness in Freshwater

As a result of the intimate contact, the long coastline, and the suitable transition zone, there has been a lively exchange of species from freshwaters to terrestrial environments and back again. Plants have evolved from a special group of freshwater green algae (Charophyceae, Coleochaetales) and diversified under the highly variable conditions on land. Insects have evolved from groups of arthropods in the transition between freshwater and land. Amphibians and reptiles have evolved from special fish in freshwater and brackish wetlands. Many evolutionary lines have been followed at different times and places.

Freshwaters have formed a corridor for the two-way dispersal of organisms between land and sea. Freshwaters also share many taxonomic groups of algae, plants, and animals with the terrestrial environment and the sea, whereas divergences are stronger between the land and the sea. Freshwater environments are surrounded by large surface areas of terrestrial and oceanic environments, which promote the emigration of marine and terrestrial species and their adaptation to freshwater environments.

Among major groups of land plants, several have secondarily returned to freshwaters, though few have reached the sea. Among liverworts, true mosses, bog mosses, horsetails, and ferns, there are many freshwater species, but no marine representatives. Among flowering plants, 1000–1400 truly aquatic freshwater species have been described from many plant families, illustrating that the secondary return from land to freshwater has occurred independently and repeatedly. The return process continues today, with more than 4000 species living an amphibious double life in the transition between land and freshwater. The sea includes only about 60 species of flowering plants with a restricted taxonomic diversity.

The diverse freshwater insects (>45,000 species) live a double life as eggs, larvae, and pupae in water and as flying

imagines dispersing and mating on land. Mayflies live for only a few days on land without taking food, whereas adult dragonflies live a long and active terrestrial life. Freshwater insects, therefore, require a suitable environmental quality in both freshwater and adjacent terrestrial environments for their sustained survival and development, though most evaluations of habitat quality in relation to species composition and richness of insects focus only on the aquatic zone.

No phylum – the highest taxonomic entity of organism below the kingdom – is found exclusively in freshwaters, but all large phyla apart from the echinoderms are represented. Virtually all types of photosynthetic organisms, including cyanobacteria, the great variety of algae, mosses, and vascular plants, are represented in freshwaters (Table 1). In contrast, the sea has very few species of gold algae, yellow-green algae, plants, and insects, and it lacks some groups of green algae (e.g., desmids and stoneworts). The sea outnumbers freshwaters only with respect to photosynthetic species among red algae, brown algae, and dinoflagellates.

The three main determinants of species richness for a specific type of environment are surface area, habitat heterogeneity, and the time history in terms of durability and evolutionary development. Considering that freshwaters cover only a few percentage of the surface area relative to that of the sea and the terrestrial environment, and considering that inland surface waters mostly have a short life time, the freshwater biodiversity is surprisingly high and must arise from the high habitat variability among individually confined water bodies and the suitable conditions for emigration and establishment of species from the large, adjacent terrestrial and marine environments.

Taking the vertebrates as an example, there are about 10,000 named species of freshwater fish and 15,000 species of marine fish. Virtually all birds and mammals depend on freshwater bodies for drinking, but a large proportion of the species also are dependent on freshwater lakes, streams, and wetlands for breeding and feeding. In Europe, about 25% of the bird species and 11% of the mammal species live their entire life or part of it in freshwaters.

Table 1 Estimated number of algal species in freshwaters and total number of all species in soils, freshwaters, brackish waters, and the sea^a

<i>Taxon</i>	<i>Freshwater species</i>	<i>All species</i>
Cyanophyta (blue-green algae)	1500	2000
Rhodophyta (red algae)	150	5000 ^c
Chrysophyceae (gold algae)	190 ^b	2000
Xanthophyceae (yellow-green algae)	550 ^b	600
Bacillariophyceae (diatoms)	5000	10,000
Phaeophyceae (brown algae)	Few	2000 ^c
Cryptophyta	100	200
Dinophyta (dinoflagellates)	200	2000 ^c
Euglenophyta	700 ^b	800
Chlorophyta (green algae)	7000 ^b	8000
Zygnematophyceae (e.g. desmids)	6000 ^b	6000
Charophyceae (stoneworts)	400	400

^aValues are presented for major taxonomic groups.

^cMarine groups.

Species in Freshwater Sediments

A global overview of organisms associated with freshwater sediments yields approximately 175,000 described species (Table 2), but the true number of species is much higher than this. The most speciose groups in freshwater sediments are insects, nematodes, and crustaceans. Among nematodes and rotifers living between the particles in freshwater sediments, there are probably many thousands of undescribed species.

Compilation of local species richness and taxonomic diversity (see Table 2) yields equally high, or often even higher, values in freshwater environments than in marine or terrestrial environments. There are apparently no systematic differences in local species richness between lakes and streams, but upstream sections of streams lack the variety of phytoplankton, zooplankton, and fish that are typical of open waters, and instead support higher species richness in the surface sediments and in the deep sediments below the streambed. The downstream parts of streams have a greater resemblance to lakes, so the similarity of species composition and richness will depend on whether entire stream systems or just certain

stream sections are compared with the lakes. The biota in porous groundwater is much deprived in species due to lack of light, degradable organic matter, and dissolved oxygen. Specialized species of protozoan and small invertebrates live here in local species numbers that are typically 10–20-fold lower than those encountered in lakes and streams (see Table 2).

Comparisons of species richness of plants and macroinvertebrates (> 1 mm) for a standard area typically show higher local and regional diversity of rivers than streams attributed to the greater habitat complexity in larger watercourses (Table 3, Williams *et al.*, 2003). Including other water bodies in the comparison for an 80 km² English region reveals that ponds per standard area have the second highest and ditches the lowest local species richness compared to rivers and streams. Regional species richness and the presence of rare species, however, are higher for ponds than for the other water bodies (Table 3). Ponds have small catchment areas and highly individual physical–chemical environments depending on local geology and land use. Rivers have extensive catchments, and local variations in soils chemistry are homogenized by the continuity of the flowing water. The ease of dispersal through rivers and streams should also lead to more uniform vegetation and fauna, whereas ponds are relatively isolated and should display greater community heterogeneity due to stochastic processes of colonization and extinction.

Table 2 Number of species described globally from freshwater sediments and the typical local range of species in lakes, streams, and groundwaters

Taxon	Global	Lake/stream	Groundwater
Bacteria	> 10,000	> 1000	> 100
Fungi	600	50–300	0–10
Algae	14,000	0–1000	0
Plants	1000	0–100	0
Protozoans	< 10,000	100–800	0–20
Crustaceans	8000	25–150	5–60
Insects	45,000	50–500	0–10
Molluscs	4000	0–50	0–10
Other invertebrates	> 12,000	30–70	5–70

Human Impacts on Freshwater Ecosystems

When evaluating the human impacts on freshwaters, this article tends to concentrate on the numerous examples of water pollution. Over the past 150 years, the environmental issues have gradually changed as new problems have appeared. Since the mid-1800s, organic pollution of streams and lakes with organic wastes from households and domestic animals has been of major concern in Europe and North America. Since 1945, the stronger focus has been on cultural eutrophication of inland and coastal waters with nitrogen and phosphorus

Table 3 Site characteristics and ranges of nitrate and total phosphorus in rivers, ponds, streams, and ditches of the 80-km² River Cole catchment, England For macroinvertebrates and plants local species richness (mean and range), total number of species and number of unique species are shown

Variables	Rivers	Ponds	Streams	Ditches
<i>Site definition</i>				
Length or number	Width > 8.25 m 17.3 km	Area: 20–20,000 m ² 65 sites	Width < 8.25 m 28.8 km	Human-made 76.6 km
Nitrate (mg N l ⁻¹)	3.2–9.7	0.1–38	2.3–19.8	0.4–17.7
Total phosphorus (mg P l ⁻¹)	0.06–1.30	0.002–2.49	0.05–5.7	0.002–0.88
<i>Local species richness</i>				
Macroinvertebrates	45.3 (18–66)	32.6 (5–69)	18.7 (3–50)	12.9 (2–35)
Plants	10.7 (6–19)	10.1 (2–17)	7.3 (1–17)	6.1 (1–14)
<i>Total species number</i>

from agriculture, towns, and industries. After 1960, acidification of low-buffered inland waters came onto the agenda due to increasing concentrations of sulfuric and nitric acids in the precipitation and changes in land use. The latest chemical concerns include trace metals and an enormous range of synthetic organic compounds of largely unknown behavior and ecological effect.

Many physical changes in the catchments are, however, more important to the existence, environmental quality, and biodiversity of surface waters than the direct water pollution. The most significant influence on terrestrial and freshwater environments is the removal of natural vegetation and the cultivation of land, which lead to immediate, profound alterations of the hydrology and nutrient cycling. These alterations are grossly enhanced when soils are drained and streams are canalized. The intimate linkage between natural wetlands and streams, which has been important for the evolution and contemporary diversity of plant and animal life, is also disrupted when surplus water directly flows to the stream through drain pipes rather than slowly percolating through the wet, sponge-like organic soils.

Most tropical countries now face the unregulated impact from all pollution sources. The most widespread problem appears to be the rising organic pollution of streams and lakes by untreated domestic sewage. However, in some regions, heavy pollution takes place from (1) extensive application of pesticides and nitrogen in plantations of bananas, cocoa, and oil palms, (2) large oil spills (e.g., Ecuador, Venezuela, and Nigeria), (3) acidification and pollution with heavy metals (e.g., copper and mercury) from mining areas and tanneries, and (4) outlet of phenolics from the timber industry. A fundamental problem is the erosion of soils deriving from the massive deforestation of tropical rainforests. Many streams have become chocolate colored from the heavy load of solids eroded by the strong rainfall. Erosion is a severe problem in agriculture, in which the fine, fertile top soils are lost. It also causes environmental problems as hydroelectric dams are quickly filled with sediments and when suspended loads in streams prevent light penetration and thereby the growth of algae, which are food for many invertebrates and fish. Furthermore, stream bottoms get clogged with fine sediments that destroy the habitats of invertebrates and the spawning banks of fish.

In many tropical countries, physical alterations of streams are still relatively few. In Ecuador, for example, streams still run in natural streambeds with meanders and rapids surrounded by strips of riparian vegetation even in densely populated areas. The hydrological cycle has been altered, however, because water is removed for irrigation, leading to artificially low discharge and current velocity during the dry season. As a consequence, the stream biota is impoverished due to oxygen depletion and smothering of the streambed following organic pollution.

Restriction of Area and Variability of Freshwater Habitats

The scene of physical changes and areal reductions of freshwater ecosystems changes among countries and with time. Changes of freshwater ecosystems have been greatest over the

past 100–200 years in densely populated countries and in regions with intense agriculture and industry. Thus, the combination of population density, resource use, and powers of technology is a suitable measure of human impact on the biosphere in general and the freshwaters in particular.

Petts (1984) defined four phases in the recent era of river modification in Europe. Phase 1, from 1750 to 1900, includes ambitious regulations of the major rivers for the purpose of navigation, flood control, and cultivation of the river valley. Phase 2, from 1900 to 1950, marks the first major technological period, during which large dams and power plants were built across major rivers. In many European lowlands, extensive drainage of wetlands and shallow lakes and channelization of streams took place, and continuous management of the dimensions of stream channels and cutting of aquatic plants were initiated. Management intensified in phase 3 from 1950 to 1980 by the use of specialized machines. During the recent phase 4, from 1980 onward, the intensity of regulation works and dam building has gone down, because most watercourses have already been exploited and public resistance has increased because of rising environmental concerns. However, most countries of the world are still in the most exploitive phase 3.

An overview of the 69 major rivers in Europe and Russia shows that most of them are strongly (40) or moderately (10) affected by dams and regulations, whereas only 19 rivers located in Arctic and northern boreal regions have remained relatively unaffected. River regulation has been undertaken to the greatest extent in Western and Southern Europe. In Belgium, Denmark, England, and Wales, the percentage of river reaches that are still in a natural state is less than 20%. In Estonia, Norway, and Poland, the rivers still have 70–100% of their reaches in a natural state.

In southern Canada and the United States, rivers are heavily regulated; those in northern Canada and Alaska have remained relatively pristine. The history of the Willamette River in Oregon is an example of how expansion of agriculture and construction of 11 dams has transformed a complex multichannel river into a simple one- or two-channel river. Over a 25-km-long stretch in the floodplain, the length of the shoreline has declined from 250 km in 1854 to only 64 km in 1967.

In addition to the shortening of rivers and streams, watercourses have become more uniform and physically disturbed. When streams are channelized, the natural variability in depth, width, current velocity, and sediment composition disappears between straight reaches and meanders and between riffles and pools. The natural dynamics of the flow channel, characterized by spatial variations of erosion and sedimentation, formation of new meanders, and the cut-off of oxbow lakes, also vanishes. Drainage of the floodplain reduces its storage capacity of water and the ability to buffer storm surge in the rivers. Moreover, drainage reduces baseflow during dry periods. Peak discharge during rainy periods introduces high physical stress and erosion in the stream channel, and low baseflow during drought increases the risk of high water temperatures, oxygen deficiency, and insufficient currents for the well-being of invertebrates and fish. All three major changes – (1) smaller area and length of the streams, (2) lower habitat diversity, and (3) greatly fluctuating flow and

higher physical, oxygen, and temperature stresses – have drastically reduced species number and population density of plants and animals.

Numerous shallow lakes and ponds in European farmland have disappeared due to drainage and filling-in. Many ponds were originally dug between 1800 and 1930 to extract calcareous sediments for the liming of acidic fields, clay for bricks, and sand and gravel for construction works and to provide watering places for cattle. In the United Kingdom, 1.2 million ponds present in 1880 declined to 0.3–0.4 million in 1990–2000. In Denmark, about 40% of lakes larger than 10 ha disappeared from 1700 to 1960 and several regions lost all large lakes. After 1980, one-third of this number have been formed as new or reestablished lakes. Similar to ponds in the United Kingdom, about 70% of the Danish ponds disappeared between 1884 and 1974. Detailed Danish studies of 2500 ponds revealed that this decline has continued recently as 40% of the ponds present in 1940 had disappeared in 1990 and only 5% had been reestablished. The net decline was larger (65%) for localities inhabited by common frogs and newts, and the decline was almost 95% for localities inhabited by rare and less robust species. The remaining ponds have been deteriorated by organic pollution and eutrophication, and retracting populations of rare frogs and newts have faced reduced dispersal that had to be overcome by intentional spread. Rare species have survived 2–3 times better in ponds that have been cleaned for nutrients and excessive plant growth compared with ponds that have not.

Large, deep lakes have experienced less physical disturbance and restriction of areal cover than streams and ponds. Exceptions are artificial reservoirs, which face great fluctuations in water level over the seasons. In Europe there are now more than 10,000 reservoirs, and about 4000 large reservoirs have dams higher than 15 m. Dams have broken the natural connection and dynamics of watercourses for the movement of water, solutes, and living organisms. However, reservoirs have generated habitats for lake organisms and new recreational opportunities.

Changing Direction: Restoring and Creating New Freshwater Habitats

Although areal reduction and the manipulation of inland waters continue in most countries, public and political priorities have changed in some wealthy countries with the goal of ameliorating some of the environmental damages caused by intensive agricultural and industrial practices.

Norway experienced serious demonstrations when a hydroelectric power plant was built across the former pristine Alta River. In Spain, the dam across the Esla has remained unused, because the inhabitants of the valley to be expropriated have refused to move. In Iceland, local “farmers” stopped early attempts to build a dam across the famous Laxa River. In Denmark, new laws now give higher priority to the development of diverse landscapes, diverse biological communities, and trout fishing. After water quality had been improved following the extensive purification of domestic sewage, new management procedures and structural changes have been implemented in many stream reaches to improve habitat

variability, to prevent catastrophic disturbance, and to strengthen the linkages within the stream course and between the stream and the floodplain. These Danish initiatives include the following: (1) removing all weirs and dams blocking the natural migration of animals; (2) bringing the streams that had been directed underground in culverts to the open surface; (3) reestablishing the variation in width, depth, and substratum between riffles and pools; (4) re-creating the former meandering patterns of straightened channels; and (5) establishing strips of natural vegetation free of pesticide spraying along the streams. Populations of brown brook and sea trout have benefitted strongly from these initiatives leading to an increase in the mean density of naturally produced trout fry per 100 stream sections in some regions from less than 1 in 1967 to more than 50 in 2008. Another initiative in northern Europe has been to restore shallow lakes and ponds that had been drained or were facing disappearance due to lack of water, filling-in, or overgrowth by littoral vegetation. Restored shallow lakes have developed a rich bird life in cases where high habitat heterogeneity has been obtained by securing variable depths, small protected coves, and islands unavailable to foxes. Large areas with shallow waters (0–30 cm) have benefitted high densities of waders. New ponds have been created in farmlands with the purpose of regaining the patchwork of small, suitable biotopes for aquatic plants, insects, and amphibians. Despite successful establishment of new ponds with amphibians, this has not compensated for the overall decline of ponds and populations of rare amphibians in Denmark, though it has prevented the extinction of some of the rarest species. The diversity of plants and macroinvertebrates in agricultural ponds has shown greater sensitivity to eutrophication than to terrestrial habitat destruction around the ponds or to an invasion of alien species. Reduction of biodiversity, however, can be predicted more accurately by combining all three environmental stressors.

Changes in the Hydrological Cycle

It is often overlooked how much the hydrological cycle has been changed by humans and the environmental implications of these alterations. Archeology, paleolimnology, and historical studies of old maps and written records in Europe reveal that the groundwater level was much higher and there used to be many more open waters in the past than today. Previously, water moved slowly and diffusively through the large water reservoirs in the soil and the wetlands before reaching streams and lakes. As a result of cultivation of soil and establishment of ditches and drains, water has taken a more direct and rapid course from the fields to the streams, resulting in huge temporal variations in discharge. Water for irrigation of crops and domestic supply to metropolitan cities is abstracted from groundwater and surface water, and this water demand has markedly increased the risk of wetlands drying up and critically low flows developing in the streams during dry periods, thereby diminishing all components of biodiversity. Because of low summer flow, about 10% of Danish streams are unable to attain the projected biodiversity; in dry regions this percentage is much higher.

Breaking the long contact between water and soil has dramatically reduced the natural purification of water by preventing the removal of surplus nitrogen and phosphorus through binding to soil particles, incorporation in new organic material, precipitation as phosphate minerals, and denitrification. In addition to the increased cultivation of crops, application of fertilizers, and discharge of sewage, changes in the hydrological cycle have resulted in the explosive eutrophication of inland and coastal waters. A few countries have tried to reestablish some of the wetlands that have been lost so extensively, thereby reinstalling the cleaning sponge between cultivated soils and streams. In most other countries, however, wetlands continue to disappear at a high rate. Spain, for example, has lost two-thirds of its wetlands since 1965 with the support of European Union subsidies to farmers.

Organic Pollution of Inland Waters

The discharge of organic wastes from towns and from livestock operations creates the classic pollution problem of inland waters. Human wastes are derived from bathing, cooking, laundry, and the flushing of feces and urine in lavatories, and discharges from agriculture include manure from the animals and food spills. Intense organic pollution can also occur from breweries, dairy factories, slaughterhouses, sugar refineries, and countless other industrial sources. In regions where water quality otherwise is high, the farming of fish, prawn, and crayfish can be common. The trout farms of Northern Europe mainly use cold spring water of superb quality, but these farms in turn pass on substantial organic pollution from food spills and fish excreta.

With the increase in domesticated animals, human populations, and the installation of water closets and sewers, there has been a profound increase in organic loading of inland waters in Europe and North America from 1850 to 1950. In several cases, the external loading of lakes has increased more than 10-fold (Figure 1). Substantial purification of domestic sewage has been established over the past 60 years. Meanwhile, wet slurry from burgeoning animal farms has presented a new source of pollution. In poor countries of the world, organic pollution has continued to grow and few attempts have been made to ameliorate the problem through the use of natural wetlands with selfpurification capacities or the construction of costly sewage treatment plants.

The organic pollution of streams increases with the density of human beings and animal livestock and the consumption of oxygen by organic matter in the water. An acceptable water quality can be reached by extensive purification, as shown by a 12-fold reduction of the biological oxygen demand at the outlet from sewage treatment plants and a 3–4-fold reduction in the stream water in Denmark from 1970 to 2000. Otherwise, the European inland waters with the low oxygen demands and highest oxygen concentrations are found in the water-rich regions in the north, where population densities are low and large areas remain uncultivated. In contrast, streams with the poorest water quality are located in intensely cultivated regions of Middle and Southern Europe, where purification remains insufficient and water is in short supply during the summer. To illustrate the differences in environmental

Figure 1 Historical development of eutrophication in Lake Fure in Denmark from 1900 to 2005. Above: Annual phosphorus loading. Inhabitants in the watershed increased 10-fold over the period. Water closets and sewers were installed in the 1930s, detergents applied in the 1950s, and sewage was diverted or underwent tertiary treatment after 1970. Below: Number of submerged macrophytes among macroalgae (black), mosses plus characeans (hatched), small (gray) and large rooted plants (white) on five occasions. Adapted from Sand-Jensen K, *et al.* (2008) 100 years of vegetation decline and recovery in lake Fure. *Journal of Ecology* 96: 260–271.

state in the 1990s, oxygen conditions were regarded as good in 97–99% of the streams in Scotland and Iceland and 64–77% of the streams in Wales, but in less than 20% of the streams in Belgium, Poland, and countries in the Balkans. Most European countries have experienced an overall decline of organic pollution in the recent decades.

Agricultural and Industrial Chemicals

An immense variety of chemical products are being manufactured, used, and released by agricultural and industrial activity. Some inorganic compounds include acids, alkalis, ammonia, chlorine, radionuclides, and heavy metals (e.g., cadmium, copper, iron, mercury, and zinc). Organic compounds are grouped under different names such as chlorinated hydrocarbons, hydrocarbons, pesticides, phthalates, and phenolic compounds. Perhaps 20,000–50,000 substances are manufactured or applied within industrial countries, and a few thousand are added each year. In most European countries, between 120 and 530 active pesticides are approved for agricultural use today. The annual usage is usually between 1 and 14 kg ha⁻¹ of arable land. Substances that are applied within a country are also detected (or their degradation products) when tested for in surface waters and groundwaters. The most common pesticides in groundwater (i.e., atrazine, desethylatrazine, lindane, and simazine) are often found in

concentrations exceeding the maximum allowable threshold ($0.1 \mu\text{g l}^{-1}$ in the European Union).

A major obstacle to pollution control is the need to first recognize the presence of potentially harmful substances in potentially harmful concentrations in relevant ecological situations. It requires a lot of money, appropriate chemical skills, and advanced analytical methods to conduct an adequate survey of the distribution and concentrations of just a small number of these trace organic chemicals. It is then even harder to evaluate the biological consequences under natural conditions. As more traditional and obvious pollution problems in developed countries are stabilized or reduced, these organic substances may perhaps become the key pollution problem in many water bodies. The pollution effects may become more apparent as the application of these new organic compounds spreads and they accumulate over time in groundwater. A Danish overview suggests that biodiversity is significantly reduced by industrial chemicals in 2% of the streams, whereas 4% of the streams are severely impacted by outlets of unknown composition. Because their biological effects are subtle, chronic, and extremely costly to verify in the complex blend of numerous compounds, living organisms, and environments, the only effective solution to the pollution problem is not to discharge the industrial pollutants at all, or reduce their toxicity, magnitude, and rate of application as far as possible. In less-developed countries, it will be impossible to monitor the release and biological effects of these trace organic compounds. Some frightening pollution events have been reported from the heavy misuse of pesticides in tropical crop production.

Cultural Eutrophication

Cultural eutrophication – predominantly due to increasing loads of nitrogen and phosphorus – leads to profound changes in the composition, biomass, and productivity of algae and plants. Lake eutrophication results in phytoplankton blooms, untransparent water, and oxygen deficiency. Eutrophication spoils the quality of bathing water and threatens the survival of bottom animals and fish. Algal blooms can include toxic algae and thereby harm animal life and become a public health risk.

Eutrophication of streams can also enhance the growth of attached macroalgae and flowering plants. Most European lowland streams have long passed the threshold at which nutrient concentrations limit plant growth. Streams in sparsely populated regions of Northern Europe and Canada can still hold such low concentrations that plant growth is enhanced at sites of elevated nutrient input. Stimulation of algal growth by eutrophication is also important in most tropical streams.

Nutrient input to watercourses has increased dramatically during the past 150 years, and it has intensified over recent decades. The sources of nitrogen and phosphorus input include (1) towns and industries, (2) scattered settlements, (3) agriculture, and (4) a background input deriving from precipitation and runoff from uncultivated areas. Input from towns and agriculture usually dominates the overall nutrient budget, but all four sources have increased because of anthropogenic impacts.

The classic examples of lake eutrophication have been documented in the vicinity of metropolitan towns. In the case of Lake Fure close to Copenhagen, annual phosphorus input increased 30-fold from 1900 to 1970 due to a 10-fold increase in the population density in the catchment, the installation of sewers, and the use of phosphorus-rich detergents (Figure 1).

Agriculture is the other major source of nutrient loading. Paleolimnological studies document the increase in accumulation rates of mineral particles, phosphorus, and organic matter in lake sediments due to increased erosion and runoff following the early cultivation of watersheds. Though nutrient input with domestic sewage has recently declined in several industrial countries, thanks to tertiary sewage treatment, agricultural sources of nitrogen have either continued to rise, leveled off, or declined slightly, but, nonetheless, occupy an increasing proportion of both nitrogen and phosphorus because of the heavy application of fertilizers and import of food to pigs and cattle (Figure 2). A large proportion (60–70%) of nitrogen applied as food and fertilizers in efficient industrial agriculture production is lost to the environment, emphasizing that highly productive agricultural systems inevitably lead to profound eutrophication of surrounding natural habitats. Nitrogen is mostly lost from agricultural fields as organic matter and nitrate in accordance with the 2–6-fold increase in nitrate concentrations in a series of English streams and groundwater reservoirs from 1920 to 1990.

An assessment of European streams reveals that nitrate concentrations have increased from 1970 to 1990 because of

Figure 2 Historical changes in the annual nitrogen input in fertilizer and organic manure to Danish farmland between 1900 and 2010. Reproduced from *Journal of Ecology* 96: 260–271.

the strong agricultural input, whereas phosphate concentrations have declined, thanks to better cleaning of domestic and industrial sewage (Kristensen and Hansen, 1994). With unregulated application of phosphorus fertilizers, phosphorus pools in agricultural soils have increased, and phosphorus will eventually get lost to inland waters by erosion of soil particles and by leaching as the binding capacity to soil minerals is surpassed. This development represents a new risk to the control of lake eutrophication in countries attempting to control phosphorus through tertiary treatment of domestic sewage. In streams exposed to strong human impact, median concentrations of nitrogen and phosphorus are typically 10-fold higher than in the few pristine streams in mountain ranges and forest regions. However, even oligotrophic waters in uncultivated areas have experienced a profound enrichment of nitrogen through increasing atmospheric deposition up to 1980. Atmospheric deposition of nitrogen has declined between 1980 and 2010, but still remains markedly above pre-industrial levels.

Anthropogenic Acidification and Recovery

Anthropogenic acidification of precipitation and surface waters commenced with the Industrial Revolution, but accelerated in Europe and North America particularly after the 1950s. Burning of fossil fuels releases sulfur oxides, which are converted to sulfuric acid in the atmosphere. High combustion temperatures in car engines and power plants release nitrogen oxides, which are converted to nitric acid. Annual wet deposition of sulfur over England increased five-fold from 1850 (approximately 5 kg S ha^{-1}) to 1977 (25 kg S ha^{-1}), but afterward has declined steeply to levels in 2010 resembling those in 1850 because of the use of cleaner fuel gases and cleaning of the emission from power plants. Also nitrate deposition, contributing to acidification, increased from 1850 ($1\text{--}2 \text{ kg N ha}^{-1}$) to 1977 ($7\text{--}8 \text{ kg N ha}^{-1}$) and has declined since then. Deposition has followed the same time course throughout Europe and the United States, though rates are highly variable among regions. The initial increase from 1860 to 1980 was much greater in Norway and Sweden (more than 10-fold) than in the United Kingdom, and the decline from 1985 to 2008 has been greater, reaching 70% for sulfur and 20% for nitric acid.

Acidification of inland waters has been substantial in the northeastern United States and southeastern Canada. Acidified regions of Europe include large parts of Finland, Norway, and Sweden; mountains in Great Britain, Poland, and the Czech Republic; and carbonate-poor, well-leached sandy soils in Belgium, Denmark, and the Netherlands. In Norway and Sweden, acidification has represented a significant national problem as thousands of inland waters have been acidified and lost their resident invertebrate species and fish. Vast forested areas have also been acidified to the extent that species diversity and elemental cycling have been grossly disturbed.

With the 70% reduction of sulfur emission during the past 30 years, acidification has been reverted in many European softwater lakes. As a typical Swedish example, sulfate in Lake Bolmen peaked in 1975–1977 (15 mg l^{-1}) concomitant with the lowest recorded acid-neutralizing capacity ($50 \mu\text{eq l}^{-1}$)

and water color (15 mg Pt l^{-1}). Since then, sulfate has declined by about three times and acid-neutralizing capacity and water color have increased three-fold. In the heavily affected Lake Saudlandsvatn, Norway, acid-neutralizing capacity has increased from $-60 \mu\text{eq l}^{-1}$ in 1980 at pH 4.7 to $20 \mu\text{eq l}^{-1}$ at pH 5.7 in 2008. Before industrial acidification commenced, acid-neutralizing capacity was around $80 \mu\text{eq l}^{-1}$ and the estimated pH was 6.7, so full “chemical” recovery has not yet been attained (Hesthagen *et al.*, 2011).

Although the increase in acid-neutralizing capacity and pH accompanying the reduced deposition of sulfur from 1980 to 2010 is easy to explain, the nationwide increase in brown-colored humic substances, particularly in the formerly most impacted regions, has been attributed to changes in land use, climate, and acid deposition. The spatial patterns, however, suggest that increasing loss of humic acids from formerly heavily acidified soils have been driven principally by reduced acid deposition during the past 30 years. This has favored solubilization of humic substances that are formed continuously and, in part, had accumulated in the acids soils during 1960–1980. These mechanisms are particularly important in soils where bicarbonate buffer systems are weaker than organic acids, soils are wet and nutrient poor, and contents of organic matter and C : N ratios are high (Clark *et al.*, 2010). As sulfur deposition eventually approaches background levels, it is likely that temperature and hydrology will dictate the direction of future trends of dissolved organic carbon as they already dictate seasonal changes.

The biological effect of acidification is in part due to the direct reduction in pH, which is intolerable to many organisms most notably bicarbonate-using plants, fish and crustaceans, mussels, and snails with exoskeletons of carbonate (see Figure 5). Associated effects arise from an altered ionic balance, high metal concentrations, and immobilization of vital nutrients. It is, therefore, expected that these harmful effects are ameliorated and biodiversity reestablished with some delay following the recent rise in acid-neutralizing capacity and pH depending on the extent and duration of acidification of the individual lake and region. In addition to the physicochemical effects, recovery is influenced by the biological recruitment. Indeed, the massive growth of acid-tolerant aquatic mosses and the reduction of isoetid plants during acidification have been reversed during recent years in Danish lakes experiencing a pH rise from about 5.2 to 6.5. In Norway, brown trout disappeared from more than 8000 inland waters, and although the most highly acidified regions have yet to show signs of recovery, this is evident in lakes when pH rises to 5.5–6.0. Also species of daphnids and net-spinning caddisflies reappear at this pH when acid-neutralizing capacity exceeds $20 \mu\text{eq l}^{-1}$ (Hesthagen *et al.*, 2011).

The rising levels of brown-colored humic substances during alkalization have caused concerns about carcinogenic byproducts of drinking water treatment and ecosystem effects. The profound humification inevitably leads to loss of submerged vegetation, altered prey–predator relations between fish species at reduced visibility, and low water quality for recreation. It remains to be seen whether brownification is a chronic problem or whether it will decline naturally during the coming decades.

Other conditions may contribute to the acidification of inland waters. Drainage and mining can expose metal sulfides (notably pyrite) to oxygen, starting one of the strongest acidifying processes that has sulfuric acid and ochre (iron oxyhydroxides) as the end products. Ochre pollution of streams leads to untransparent waters, smothering of sediments, and a steep decline in the diversity of plants, algae, macroinvertebrates, and fish. Eggs of trout and salmon suffocate from lack of oxygen due to reduced water flow through spawning banks, and adults suffer from starvation and toxicity of ferrous iron ($>1 \text{ mg Fe l}^{-1}$). In streams draining pyrite-rich soils, pH may decline (3–4) and iron may increase to the extent that most multicellular organisms disappear.

Biological Quality of Freshwater Ecosystems

Anthropogenic impacts on freshwater ecosystems lead to loss of lakes and streams, changes in the hydrological cycle, physical disturbance, and water pollution. Streams have presumably experienced the entire range of physical and chemical influences, whereas major lakes mostly have experienced acidification, eutrophication, and pollution by organic matter and industrial chemicals.

The resulting changes in species composition, species richness, and elemental cycles in freshwater ecosystems are complex, have several causes, and can be evaluated at different levels. Major changes have taken place in almost every stream due to regulation, management, and pollution, and in many regions and countries, it is impossible to find pristine streams to use as a reference for baseline conditions and high biological quality.

The natural variability among lake types has dropped. Historic and paleolimnological studies of Danish lakes, for example, show that the former full range of lake types from oligotrophy to eutrophy has been restricted owing to widespread eutrophication such that there are very few oligotrophic lakes left. Though probably more than 80% of Danish lakes, belonging to the oligotrophic, mesotrophic, and eutrophic categories, had a rich submerged vegetation 100–150 years ago, less than 15% of all lakes today have sufficiently clear water to permit submerged plant growth. With the exception of Finland, Norway, Scotland, and Sweden, oligotrophic, clear-water lakes have become rare across the entire European continent.

Less variation in lake and stream types will restrict beta and gamma diversity and, in particular, reduce population densities of those species that prefer undisturbed, oligotrophic habitats. Likewise, in European terrestrial vegetation, many oligotrophic and disturbance-sensitive species characteristic of heathers, *Sphagnum* bogs, and nutrient-poor grasslands have become rare and are threatened by local or regional extinction. In many individual lakes and streams, profound alterations of species composition and abundance can be documented over time. Recent changes are small, however, if one evaluates only whether the individual species still exist within the national borders or have survived globally. A few refugia of relatively undisturbed lakes and stream reaches are still likely to exist, and they may support small populations of those species that

Figure 3 Historical changes in the number of Danish stream localities with different *Potamogeton* species during three studies of the same 13 localities in 1896, 1996, and 2004–2009. Adapted from Figure 1 in Riis and Sand-Jensen (2001), *Freshwater Biology* 46: 269–280, with permission from John Wiley & Sons.

otherwise have declined dramatically in geographic range size and local abundance. Species extinction is a slow process, and long before the last individual finally dies, the species has lost its significance in the ecosystems and in human perception of nature. The continued decline of *Potamogeton* species in regulated streams is a clear warning that extinction can continue although recent steps have been taken to improve water quality (see Figure 3).

Decline in Freshwater Species in Europe and North America

A large proportion of extinct, threatened, and rare species in Europe and North America live in freshwaters. Species in streams and ponds have been most strongly affected by human impact. In North America, 11–14% of the mainly terrestrial birds, mammals, and reptiles are among the extinct, threatened, and rare species (Table 4). Among freshwater amphibians, fish, crayfish, and mussels, the percentages are particularly high (28–73%). No less than 103 species of North American freshwater fish are classified as endangered, 114 are threatened, and 147 deserve special attention. These species represent about one-third of all fish species. Twenty-seven species have gone extinct over the past 100 years from habitat loss, chemical pollution, introduction of exotic species, hybridization, and overfishing (Allan, 1995).

Table 4 Percentage of species within selected groups of freshwater or mainly terrestrial animals on the Red List in North America (by 1990) and Denmark (by 1996)^a

Group	North America	Denmark
<i>Freshwater habitats</i>		
Amphibians	28	36
Fish	34	39
Crayfish	65	–
Unionid mussels	73	–
Caddisflies	–	32
Dragonflies	–	42
Mayflies	–	50
Stone flies	–	40
<i>Terrestrial habitats</i>		
Birds	11	37
Mammals	13	30
Reptiles	14	25
Beetles	–	26
Butterflies	–	49
Moths	–	16

^aSpecies on the Red List are recently extinct, threatened, vulnerable, or rare. Red Lists focus on particular vulnerable groups often highly valued by humans.

The European status of freshwater species is worse because of a long history of strong human impact. Europe is relatively poor in species of freshwater fish (approximately 250) compared with North America (approximately 850), Africa (1800), and the Amazon region (2000 species). Species numbers are particularly low in Northern Europe (e.g., 34 indigenous species in Denmark), whereas they are much higher in Middle and Southern Europe. The Volga and the Danube include 60–70 species each, or 25% of the entire European fish fauna. In European countries, about one-third of all fish species are on the IUCN Red List, much like in North America. In the global status, 20 European species are threatened, susceptible, or rare.

On both continents, many genetically isolated stocks of salmon and trout confined to certain stream systems are threatened by eradication, or they have already been lost from a variety of threats such as river regulation and construction of dams that prevent upstream migration and that destroy spawning grounds. Discharge of wastewater from agriculture, industry, and towns has also contributed to the loss, as have acidification in areas with poorly buffered waters, interbreeding with hatchery-reared individuals, and overfishing in the ocean.

The Atlantic salmon was once very common along its range of distribution from Iceland to Portugal. It has now disappeared from many major rivers on the continent, and the annual catch has dropped profoundly. The large salmon population in the Rhine supported an annual marketed catch of more than 100,000 individuals in the late 1800s. The species declined during the 1900s and went extinct in 1957, but was later reintroduced from an artificially reared stock. Atlantic salmon was lost from Danish rivers during the 1900s, apart from very small indigenous populations surviving in four larger rivers in western Jutland.

DNA studies of preserved salmon scales from the extinct and extant Danish populations have shown that the individual

rivers had genetically distinct populations. These differences were much larger between populations in Denmark, Scotland, and Sweden than between populations in neighboring rivers. Thus, restocking with foreign salmon was abandoned, whereas initiatives were taken to secure and perhaps disperse the small, national salmon stock, which is probably better adapted to the local environmental conditions and food sources than are the foreign salmon. Although Atlantic salmon may still be part of the fauna in several countries of continental Europe, it has lost, at least for the moment, its role as an enjoyable catch and an important part of the ecology of the streams. Moreover, the original high genetic diversity among the many local populations of individual rivers is definitely gone. Nonetheless, systematic rearing of the small surviving salmon stocks from individual Danish rivers during the past 20 years has been highly successful and reestablished healthy, very substantial salmon populations that are now exploited by sportfishing.

Red Lists and Historical Development in Streams of Denmark and the United States

Red Lists focus on threatened, vulnerable, and rare species and usually include those species that have disappeared recently. Among the five studied groups of freshwater insects, the percentage of red-listed species of all national species in Denmark ranges from 32% for caddisflies to 50% for mayflies (Table 4). Freshwater fish have 39% and amphibians have 36% of all national species on the Red List. Among terrestrial insects, the percentages vary from 16% for moths to 49% for butterflies. Birds and mammals have 37% and 30%, respectively.

Overall, the percentage of species on Red Lists is high for three reasons. First, the most vulnerable groups are more often included than the least vulnerable groups. Second, many species are naturally rare. Third, many species are present in very small numbers, because natural habitats have experienced profound areal restriction and deterioration. Although the percentage of red-listed species tends to be higher for freshwater than for terrestrial species, this tendency disappears if more common groups of freshwater invertebrates such as dipterans, oligochaetes, and polychaetes were included.

Consequently, Red Lists have several weaknesses because they are selective and qualitative, and the intensity of search for rare species has increased over time. Red Lists do not give quantitative data on the abundance of species, and they can describe only the temporal development in crude ways, provided evaluations are repeated at suitable intervals.

Many evaluations of species development, however, suffer from the lack of suitable historical description of species distribution and abundance. If such studies indeed exist, they did not use exactly the same methods and survey intensity and are therefore open to critique, even though differences may be very profound and without reasonable doubt are real.

A historical analysis of *Potamogeton* (a large, aquatic plant genus) in 13 localities in Danish lowland streams, for example, revealed the existence of 6.7 species per locality and 16 species altogether in 1896 (Figure 3). In 1996, the mean number was 2.8 species per locality and only seven species were present. The decline has continued, resulting in only 1.9

species per locality and six surviving species in 2009, which implies that recent improvements in water quality and managements have been insufficient or recolonization of species from undisturbed river or lake refugia is no longer possible. Several of those species that have disappeared from the 13 localities have become extremely rare throughout the country. The same type of development has taken place in other lowland regions of northwestern Europe such that some species (e.g., *Potamogeton acutifolius*, *Potamogeton filiformis*, and *Potamogeton zosterifolius*) have become rare over wide geographic areas. The *Potamogeton* species that are still common are fast-growing eutrophic species of high dispersal capacity that have best been able to cope with the high disturbance and nutrient richness of contemporary streams. It is noteworthy that plant species in streams display an overall positive relationship between geographic range size and local abundance, resembling the pattern for terrestrial herbs and animals. Species of low geographic range size and low local abundance face a double jeopardy of extinction because they grow in just a few places and are infrequent at sites where they do occur. Stochastic loss of some habitats and degradation of others should therefore have a strong impact on these species, because their few and small populations make them susceptible to further losses and reduce their ability to disperse to new suitable places. In contrast, widespread species of high local abundance have a double security, because they have a higher probability of surviving stochastic changes and spreading to new habitats.

The channelization of streams has been shown to have a significant influence on riparian plant assemblages by reducing local diversity associated with a steeper bank slope and reduced flooding. Moreover, undisturbed streams are also spatially more heterogeneous and richer in submerged species than streams that are cut regularly.

Freshwater insects have undergone a similar decline of species richness, number of ecological types, and number of occupied habitats. About 20 species of the 285 Danish species of caddisflies, dragonflies, mayflies, and stone flies have gone extinct between 1900 and 1989. A larger number of 76 species are either threatened, vulnerable, or rare. The red-listed species often require high water quality and have long life cycles that are sensitive to disturbance. The historical development has, therefore, led to a more stereotypic composition of both plant and macroinvertebrate communities with the same few robust species dominating at most stream sites. In contrast to the *Potamogeton* vegetation, however, insect diversity has improved in Danish streams following reduced organic pollution since 1980 and species have spread from local surviving populations both within and between neighboring river courses. Physical impact by channelization and intense management of streams still remains a main factor for depriving diversity of macroinvertebrates in about 23% of Danish streams, whereas about 46% of the streams are still deprived of species by organic inputs from scattered settlements, farms and fish farms in open areas, and outlet from sewer systems during heavy rainfall.

There are very few similar historical evaluations of species distribution and abundance. What come closest are studies of agricultural areas of the United States Midwest. These demonstrate profound reduction of habitat quality, species richness, and abundance of stream invertebrates and fish between

1950 and 2000 as a result of removal of most of the natural riparian forest vegetation, stream regulation, and alteration of water chemistry. Indices of stream quality decline with the intensity of cultivation in the catchment, and this is accompanied by a predictable decline in species richness and feeding types of invertebrates and fish. Predominantly robust, generalist species have survived in the stream communities. Fish that specialized on insects have disappeared, whereas omnivorous fish have survived. The historical development of plants and animals, therefore, has many similarities in the lowland streams of Europe and the United States, because all macroscopic organisms have been strongly influenced by cultivation and agricultural practices.

Biological Consequences of Organic Pollution and Agricultural and Industrial Chemicals

Organic pollutants give rise to deoxygenation and release of ammonia and other mineral nutrients in the water due to high microbial activity. Organic pollution leads to unhealthy aquatic conditions, high nutrient levels, untransparent water, and smothering of sediments. These conditions are detrimental to the survival of invertebrates and fish, and highly oxygen-sensitive groups of insects such as beetles, caddisflies, mayflies, and stone flies, as well as salmonid fish, may disappear almost entirely. Also, the diversity of feeding groups of macroinvertebrates declines as stony substrata for algal grazers are smothered, coarse terrestrial detritus for shredders becomes insignificant relative to the accumulation of organic mud for deposit feeders, and large predators with long life cycles find it hard to sustain episodes of oxygen depletion. Thus, organic pollution is accompanied by a general loss of species richness, taxonomic diversity, and functional diversity of macroinvertebrates, in addition to the appearance and dominance of particularly robust species (e.g., tubificid polychaetes and chironomids) in exchange for the loss of many more sensitive species (Figure 4).

The biological changes are principally the same in temperate and tropical streams. The macroinvertebrate indices originally developed to describe organic pollution in temperate streams work well in tropical streams. The obvious reason is that the taxonomic composition of orders and families of macroinvertebrates does not differ greatly between temperate and tropical streams. Taxonomic similarity is particularly high between temperate lowlands and tropical highlands. The warm tropical lowland streams may have a high sensitivity to organic pollution because of low oxygen solubility, fast microbial degradation, and high invertebrate metabolism. Tropical highland streams also may be more sensitive to organic pollution than temperate streams because of the reduced partial pressure of oxygen at higher elevations, whereas temperatures resemble those in temperate lowland streams.

Domestic wastewater contains many chemical stressors in addition to the oxygen-consuming organic material. Sensitivity of organisms to low oxygen often goes hand-in-hand with the sensitivity to industrial chemicals. Similarly, sensitivity to acid waters usually changes in parallel with the sensitivity to heavy metals. Chemical stressors are lethal at high

Figure 4 Composition of macroinvertebrate communities in small highland streams in tropical Ecuador as a function of organic pollution from villages, resulting in a lower minimum oxygen saturation in the water: (a) number of macroinvertebrate families; (b) proportion of oxygen-requiring taxa of caddisflies, mayflies, and stone flies (EPT taxa) to taxa that require less oxygen (TCP taxa), such as Tubificidae and species of *Chironomus*. Data from Jacobsen D (1996) *Ecology and Environmental Status of Tropical Streams in Ecuador*. Copenhagen: Freshwater Biological Laboratory and Danida, Danish Foreign Ministry.

concentrations, and sublethal disturbance of body form, reproduction, neural function, and behavior occurs at lower concentrations. Among *Chironomus* species, for example, the proportion of individuals with deformed mouthparts increases with the level of pollution. Among net-spinning caddis larvae, the proportion of abnormal, incomplete nets increases with the concentration of toxic aluminum. These sublethal effects will eventually lead to a decline of populations due to reduced growth and survival compared with more resistant species. However, under very severe oxygen deficiency or high concentrations of toxic chemicals, no species of higher life forms among fish, invertebrates, and plants are capable of surviving, and only microorganisms will remain. Chemically polluted streams and ponds without any higher life include habitats with high concentrations of cadmium, copper, zinc, and ferrous iron.

The immune and hormone systems of animals can be disturbed by exposure to organochlorine compounds (e.g., dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs)), nonylphenols and octylphenols of industrial detergents, and an estradiol component from degradation of contraceptive pills. In water bodies with a high proportion of sewage effluents, such compounds can apparently lead to the development of hermaphrodite individuals of roach and rainbow trout, abnormally small testicles in alligators, and feminization of populations of terns and gulls feeding on

aquatic animals. Estrogenic effects have received great attention because human populations have been showing increasing frequencies of testicle cancer and decreasing numbers of viable sperm cells over the past 50 years in Scandinavia.

The great variety of pesticides now being found in surface waters are also potentially dangerous because they have been manufactured to be deadly poisonous in trace amounts to fungi, insects, and plants. Insecticides target the most species-rich group of animals on land and in freshwater. For the time being, however, the broad-scale environmental significance of pesticides is largely unknown. There are suggestions that intense application of pesticides in some regions can account for an impoverished insect fauna in streams, where other pollution sources have largely been eliminated. This is the situation in 2–6% of Danish streams.

Biological Consequences of Lake Eutrophication

Lake eutrophication influences ecosystem structure and functioning as well as the distribution and abundance of most species. This fundamental influence is the result of the primary role of nutrients in boosting the biomass and productivity of phytoplankton, setting the scene for many structural and functional regulations.

The attitude toward cultural eutrophication changes with its magnitude and the public interests in different regions. In lowland regions of Europe and North America, substantial eutrophication has shifted the natural wide range of lakes to a higher nutrient level that encompasses conditions from mesotrophy to hypereutrophy. Water purification aims at improving hypereutrophic lakes and moving them to eutrophy, such that most lakes may occupy the narrow range from mesotrophy to eutrophy with no lake being unpolluted and no lake being extremely polluted. As a consequence, species assemblages have become more stereotypic as the susceptible species of oligotrophic habitats, and in some cases also the extremely robust species of hypereutrophic habitats, have become very rare. Full control of pollution and the ecological disturbance associated with agriculture, fish farming, forestry, and recreational use, which may be needed to maintain pristine, oligotrophic, clear-water lakes, has rarely been implemented.

Social and environmental priorities are different in other societies. In Southeast Asia, for example, the focus is more on fish production and less on esthetics and the protection of rare species. A small lake that is heavily fertilized by village sewage may be a valuable source of fish that feed on the thick algal soup and that are tolerant to periods of deoxygenation.

The Case of Lake Fure and Other Hardwater Lakes

The 100-year development of Lake Fure in Denmark can serve as an example of the widespread, accelerated nutrient loading of temperate lakes followed by recent reduction of loading rates (see Figure 1). The long-term evaluation for this lake matches the long water residence time (10 years) and the slow numerical response of macrophyte communities in this naturally mesotrophic, hardwater lake.

Annual external phosphorus loading of the lake increased from 1.3 tons of P in 1900 to 37 t in 1969.

Until the late 1940s, the lake had managed to tolerate the increased loading relatively well because of the efficient sediment binding of phosphorus to calcium carbonates and iron oxyhydroxides. The bottom waters had remained oxic and iron-bound phosphorus had stayed in the sediments. With the accelerating phosphorus load during the 1950s and 1960s, extensive phytoplankton blooms developed, leading to oxygen-free bottom waters and release of iron-bound sediment phosphorus. Following diversion and tertiary treatment of the sewage in 1969, the external phosphorus loading has gradually declined to 2–3 tons of P in 2008.

The mean Secchi depth during summer was about 5–6 m from 1900 to 1940, but it has fluctuated between 1.5 and 3.2 m in the 1970–1980s. With the reduced phosphorus loading in the 2000s, the mean Secchi depth has increased to 3–5 m. The number of phytoplankton species has remained approximately constant between 70 and 85. However, species within particularly nutrient-demanding groups typical of eutrophic lakes (e.g., blue-green and chlorococcalean green algae) have increased from 17 to 39, and species typical of oligotrophic lakes (e.g., chrysophytes, desmids, and certain dinoflagellates) have declined from 32 to 13. The same changes in dominant algal groups are found in broad-scale comparisons among oligotrophic and eutrophic lakes.

Species richness of submerged macrophytes in Lake Fure before eutrophication commenced was 37 species, including 18 rooted flowering plants, 11 characeans, five mosses, and three macroalgae. Tall flowering plants grew from shallow water to the depth limits at 8 m, but dominated the vegetation down to 5 m depth. Small flowering plants, characeans, and mosses formed a mixed carpet of vegetation below the canopy of large flowering plants, whereas characeans dominated from 5 to 8 m.

In 1983 and 1993 only 12–13 of the original 37 species remained, whereas three new species of pollution-tolerant green macroalgae had appeared. Most small flowering plants and characeans and all mosses had vanished. Eight large species of canopy-forming flowering plants survived in the turbid lake because they can compensate for the poor light conditions by exposing the leaves close to the water surface. Depth distribution of all original submerged macrophyte species was restricted from 8 to 2 m because of the reduced light penetration.

During the recent oligotrophication of the lake, species richness increased to 25 in 2005, depth limits grew to 4–7 m, and a few characeans and mosses reappeared, whereas bottom mats of the pollutant-tolerant macroalgae remained dominant in the now nutrient-rich sediments.

Although internal phosphorus concentrations, phytoplankton biomass, Secchi transparency, and macrophyte depth penetration and species number are obviously reversible following reduced external phosphorus loading, macrophyte species composition is not reversible, at least not in the time frame of 30 years. About 10 small oligotrophic species susceptible to shading and competition had vanished and did not reappear. Their reestablishment is either impossible or just extremely slow because widespread eutrophication has eradicated them across large regions and they can recolonize only from small, distant refugia.

Broad-Scale Comparisons and Whole-Lake Experiments

Other individual lake studies basically tell the same history of eutrophication. In the large lakes, however, the role of the littoral zone and bottom plants is small, and emphasis is more on the increase of phytoplankton biomass, loss of bottom fauna, and alteration of fish communities. In most lakes, phosphorus is the main nutrient-limiting phytoplankton biomass, but in some lakes, the importance of phosphorus and nitrogen as limiting nutrients alternates with the seasons or nitrogen plays the major role.

In lakes with a small magnitude or a short period of cultural eutrophication, rapid recovery was observed upon reduction of nutrient loading, because only small nutrient pools had accumulated in the lake bottom. Recovery also is fast and more complete when water renewal is high, and when large proportions of unpolluted water are available from undeveloped mountain and forest areas such that nutrients can be flushed from the lake (e.g., Lake Washington, United States).

Case studies of individual lakes, comparisons among many lakes, and controlled whole-lake fertilization experiments all show strong positive relationships among nutrient availability, phytoplankton biomass and productivity, zooplankton and fish production, light attenuation in the water column, and risk of anoxia in bottom waters. Predictions of phytoplankton biomass based on external phosphorus loading and water renewal are often excellent for lakes within a region of the same climate and soil geology and for lakes where nutrient inputs are precisely known. These results suggest that biotic differences do not play a major role for the biomass of phytoplankton. It has therefore been argued that the lower accuracy of predictions observed among lakes from different regions and studies may result from methodological differences and uncertainties rather than from the influence of biological differences in the food webs. In shallow lakes, however, wide shifts can take place from transparent lakes of low phytoplankton biomass and high macrophyte cover to more turbid lakes of higher phytoplankton biomass and marginal macrophyte cover, even though phosphorus loading remains approximately the same. In shallow lakes, rooted macrophytes and attached animals have the potential to exert considerable control on the communities in the open waters – in part through internal alterations of nutrient cycling. The same intimate interactions between organisms and processes at the bottom and in the open water are not possible in large, deep lakes.

Resource and Predatory Control in Food Webs

In many lakes, phosphorus stripping and the diversion of sewage have reduced nutrient input and greatly improved lake quality (Figure 1). In some lakes, improvements of lake quality have been small presumably because of high internal nutrient circulation. To reduce sediment release and internal water concentrations of phosphorus, several methods have been attempted. One principle is to remove P-enriched cultural sediments by pumping them up. Another principle is to increase the P-binding capacity in the sediment by adding aluminum. The immediate effect is very profound, but over time, the binding capacity of aluminum flocks declines and much phosphorus is released again. Iron addition conducive

to efficient phosphorus binding to iron oxyhydroxides is problematic because permanent oxic waters are required through, for example, continuous aeration of the bottom waters.

In shallow lakes, biomanipulation has had the objective of reducing the number of planktivorous fish, which eat the large zooplankton (especially daphnids), and thereby hopefully reduce the biomass of phytoplankton through enhanced zooplankton grazing. The additional goal is to increase the cover of submerged vegetation, which can directly reduce sediment release of nutrients, impede phytoplankton development by shading, and provide refuge to daphnids.

The success of attempts to reduce phytoplankton blooms and improve water clarity by internal manipulation of sediments and food webs is variable, and some positive short-term effects for up to 10 years by removal of planktivorous fish have not been sustainable in the long term. Addition of predatory fish (e.g., pike) with the aim of reducing planktivorous fish and phytoplankton has been unsuccessful. The successes and failures of biomanipulation are widely debated. The view that grazing control on phytoplankton is high in lakes with an even number of trophic levels in the food web and low in lakes with an odd number of levels has not only received some support, but also attracted growing opposition because of the following: (1) predictions based on the concept are poor, (2) trophic levels and numbers of links are difficult to define, and (3) many species are omnivorous, show ontogenetic and opportunistic changes in food preference, and cover more than one trophic level and habitat (i.e., both water and sediment). Moreover, there is a strong positive relationship from nutrients and resource levels to biomass and productivity of phytoplankton, zooplankton, and fish because of the need to transfer energy and matter from low to higher trophic levels.

Many studies clearly demonstrate a strong role of predators on size composition and species abundance of prey organisms, and they show behavioral alterations of predators and prey to increase their own growth and survival. These flexible biological responses, however, do not imply that the main control of the combined biomass and productivity of all the species at each trophic level is exerted by predation. Overall, predatory fish have a small cascading trophic effect through the entire food web and a minor influence on phytoplankton biomass and water transparency. As a consequence, there is no easy technical or biological fix to ameliorate lake eutrophication, but various techniques may assist the effect of sustained reduction of external nutrient input with the aim of reducing troublesome phytoplankton blooms.

Species Richness and Lake Trophy

Species richness increases with habitat area and heterogeneity. The increase in species richness (S) with habitat area (A) is often predicted by the equation $S = \text{constant} \times A^z$. The z value depends on the organisms, the spatial range of the study, and the habitats, and there is no single mechanism that can account for the variability of z . However, low z values are consistent with high immigration rates, low extinction rates, and a low rate of increase in additional habitat with increasing area. As a consequence, very small z values are predicted for bacteria, microalgae, protozoa, and zooplankton. Indeed, the

z values predicting crustacean zooplankton species richness are only 0.054 for European and 0.094 for North American lakes. A low z value of 0.10 for submerged macrophytes in Scandinavian lakes is also consistent with their widespread occurrence.

In contrast, species richness of fish in lakes of four different regions in Canada and the United States shows much higher z values (0.16, 0.22, 0.36, and 0.37) consistent with the more restricted geographic range size, smaller local abundance, and greater risk of extinction of fish following disturbance or restriction of natural habitats. As a consequence, risks of local, regional, and global extinction are high among fish and low among microorganisms and plankton organisms, with aquatic plants and insects probably holding an intermediate position. Some large crustaceans and molluscs presumably resemble the fish by having a low rate of dispersal and including several species of restricted geographic distribution (e.g., the freshwater crabs and prawns on tropical oceanic islands).

Changes in ionic composition and nutrient concentrations of freshwaters are superimposed on changes in habitat area and heterogeneity. Water chemistry is not independent of habitat area and heterogeneity, since small lakes include a higher proportion of low pH, low-calcium, and nutrient-poor waters than do large lakes. In many studies of the influence of pH and lake trophic on species richness, it is not possible to fully compensate for the influence of habitat area and heterogeneity.

The most diverse conditions and highest species richness often are found under mesotrophic conditions, where many species can coexist at different sites and depths within the lakes. Thus, high habitat heterogeneity is probably important for the common peak of species richness under mesotrophic conditions. For example, many free-living and attached species adapted to different conditions of light, temperature, and exposure can replace each other along depth gradients from shallow to deep waters. Under very oligotrophic conditions, many algae and plant species are nutrient limited, and low primary production places an energetic restriction on the diversity and density of invertebrates and fish. In contrast, under hypereutrophy, many species are restricted by the lack of light and oxygen in deep waters, and special adaptations are required for survival in very muddy sediments.

Two other conditions contribute to the decline of species diversity under hypereutrophic conditions. First, the natural local variability between unfertilized and fertilized sites disappears with the overall nutrient enrichment at all sites accompanying eutrophication. Second, hypereutrophy is exceptional for most species, which have evolved over many millions of years of no or weak human impact. Species richness is expected to be highest in those common habitat types that have had the most widespread and long-term natural occurrence, because there has been time and room for speciation. Hypereutrophic lakes, which are common today, have been exceedingly rare during most of the development of freshwater species.

It is noteworthy that lake ecosystems are much more sensitive to environmental deterioration and catastrophic declines of organisms by eutrophication than terrestrial ecosystems for at least four reasons. First, nutrients tend to stay

in circulation within the lake boundaries. Second, phytoplankton responds by a steep increase in biomass and productivity. Third, photosynthesis and growth of algae and plants are restricted to the uppermost surface waters because of the impoverished light conditions. Fourth, the risk of oxygen depletion is very high because of low oxygen solubility in the water. Therefore, species richness within many groups of organisms declines in hypereutrophic lakes because of reduced habitat heterogeneity, restriction to the distribution of organisms, and development of stressful and highly variable environmental conditions with respect to light, oxygen, pH, and sulfide.

Biological Consequences of Acidification

Acidification up to 1980 initiated complex chemical and biological changes in surface waters and catchments with poorly weathered rocks and thin soils. The acidification of freshwater habitats was also accompanied by acidification of terrestrial ecosystems in the catchments, leading to a widespread regional decline of biodiversity.

Whole-lake experiments involving acidification to pH 5 demonstrate that damage to ecosystem functioning is of secondary concern compared to impoverishment of the biotic communities. Although many phytoplankton algae disappear, the remaining algae can maintain biomass and primary production at the same level, largely regulated by the input of phosphorus and water renewal. The rate of decomposition is governed by primary production and not by pollutants. However, the complete disappearance of large invertebrate detritivores upon acidification may lead to the accumulation of detritus and over the long term reduce plant production based on recirculated nutrients. Overall, nutrient cycling was not disrupted in whole-lake experiments, but nitrification declined at pH values below 5.4.

Acidification of the watershed changes ionic composition and may reduce the availability of phosphorus in soils and surface waters. Soil acidification increases the leaching of base cations, and it has specific effects on the solubility of aluminum and phosphate. Chemical weathering of aluminum minerals is enhanced under acid conditions. However, soluble forms of aluminum ions may precipitate with phosphate at the proper pH, leading to "oligotrophication." As a result, lakes in acidified watersheds may become very clear from the enhanced phosphorus limitation of phytoplankton growth, and certain acid-tolerant aquatic mosses (e.g., *Sphagnum* spp.) and filamentous green algae (e.g., *Mougeotia* spp.) may spread across the lake bottom to greater depths. Only a few vascular plant species can tolerate highly acidic conditions (e.g., *Juncus bulbosus*).

Species diversity and abundance decline within most groups of organisms upon acidification, though some groups are much more sensitive than others and distinct differences exist among species in their tolerance to acidification (Figure 5). In acidified regions of Europe and North America, many lakes lost 30% or more of the species in some taxonomic groups before 1980. Among planktonic and benthic microalgae, desmids – a group of green algae – prefer buffer-poor waters of low pH and low-calcium content, and they are

Figure 5 Cumulative frequency distribution of minimum field observations of pH for 46–370 aquatic taxa within different taxonomic groups. Adapted from Schindler DW (1991) Aquatic ecosystems and global ecology. In: Barnes RSK and Mann KH (eds.) Fundamentals of Aquatic Ecology, 2nd edn, pp. 108–122. Oxford, United Kingdom: Blackwell.

often accompanied by a few acid-tolerant species of blue-green algae, dinoflagellates, diatoms (e.g., *Eunotia exigua*), green algae (*Chlamydomonas acidophila*), and euglenophytes (*Euglena mutabilis*). In contrast, most species of diatoms, chlorococcalean green algae, and blue-green algae prefer well-buffered waters of neutral pH. Among planktonic rotifers, copepods, and daphnids, only a few species tolerate acid waters (less than 4–5), so the planktonic food webs become simple. The tolerant species can utilize the vacant ecological niches left by others, thus maintaining a relatively constant zooplankton biomass despite the decline in species richness.

Many snails, mussels, and crustaceans (e.g., crayfish) are highly sensitive to acidification due to problems in maintaining the ionic regulation of sodium, chloride, and potassium and in forming the exoskeleton of calcium carbonate or calcium-chitin when pH and calcium concentrations are low. Higher calcium concentrations can help in maintaining membrane integrity, reducing gill permeability to salt loss, and ensuring the construction of shells. Several metal toxins such as aluminum mobilized under acidic conditions have the opposite influence.

Among insects, the most acid-tolerant species include surface-breeding beetles with a hard exoskeleton and certain stone flies and caddisflies with a low metabolism and mostly lacking thin-walled body parts. In contrast, mayflies with their large, thin gills are often highly sensitive to acidification. The decline in species richness of insects is not as pronounced when acidic conditions occur in waters rich in humic substances, which can bind and detoxify the metal ions mobilized at low soil pH.

A common result of acidification is the dramatic loss of fish. Former acid-stressed regions of Scandinavia, the Adirondack Mountains (USA), and La Cloche Mountains (Canada) showed a steep decline in fish species as lake pH declined from 8 to 4, and many lakes with pH less than 5 became fishless. In Norway, brown trout disappeared from more than 8000 lakes. With the reversal of acidification, fish populations are slowly coming back. The decline in fish species richness with reduced pH is much less pronounced in subtropical Florida lakes and in tropical lakes. The presence of more acid-tolerant fish species in warm lakes may be due to a much slower and more gradual decline in pH over time and, accordingly, better opportunities of genetic adaptations to low-pH waters. Also, Florida lakes have lower concentrations of aluminum and free mineral acids, longer growing seasons, and no episodic input of acids resembling the massive acid input of north temperate lakes during snowmelt.

Fish studies in north temperate lakes showed that eggs, embryos, and larval stages of fish are more sensitive to acidification than the adult stages. As a consequence, young generations may vanish upon acidification, whereas old fish may remain for a while. Populations will eventually die out unless young fish are continuously stocked. Salmonids and cyprinids with a high metabolism and a large gill surface appear to be more susceptible to acidification than fish with a low metabolism and a low gill surface (e.g., eels). A critical phase for the well-being of fish and invertebrates is the maintenance of efficient oxygen uptake and ion regulation across the gill surfaces.

Ecosystem Functions and Explanations

Ecosystem functions have proven to be more resistant to acidification than species changes. Species assemblages are often plastic enough to maintain ecosystem functions under quite extreme stresses, although only a few species survive. For example, plant productivity continued in a dense monospecific vegetation of *J. bulbosus* growing in a highly acidic, temperate stream (pH 2–3) from a lignite mining area with intense pyrite oxidation, whereas neighboring alkaline streams (pH 6–7.5) contained a mixed assemblage of about 10 rooted plant species. Similarly, phytoplankton biomass and production were unaffected in lakes polluted with strong acids and trace metals from smelters. Phytoplankton and other microorganisms are also locally abundant and are easily dispersed, such that highly pH-tolerant species will rapidly show up and multiply in recently acidified localities.

Some ecosystem processes, however, may decline or disappear entirely under very acidic conditions. At pH values

below 5.4–5.7, ammonium begins to accumulate due to the cessation of nitrification. Therefore, the loss of internally produced nitrate through denitrification will stop. However, the enhanced atmospheric deposition of nitric acid and sulfuric acid will permit the microbial activity of denitrifiers and sulfate reducers in oxygen-free sediments and, thereby, generate alkalinity in the water bodies.

The biotic communities of lakes and streams are strongly damaged and impoverished by acidification. The most vulnerable species appear to be organisms with year-long life cycles and poor dispersal, such as large invertebrates and fish. These groups are also the less speciose, particularly in northern water bodies, which means that there is little redundancy in the food webs to prevent pH-sensitive species of large detritivores, plankton-eating fish, and predatory fish from being replaced by pH-tolerant species. Fish and crayfish, which are highly valued by humans, are therefore easily damaged. Even bird populations such as dippers, osprey, and pied flycatchers may vanish from the lack of food or the formation of thin-shelled eggs while feeding on calcium-deficient and aluminum-rich prey.

Overall, surface waters of very low pH represent a special environment to which very few species have become adapted as a result of (1) the direct stress at low pH, (2) the unsuitable ionic composition, (3) the toxic metals, and (4) the rarity of these habitats during the evolution of aquatic organisms, particularly in temperate and subarctic regions.

Conclusions

Freshwaters of high quality are essential to humans for domestic and agricultural uses. Freshwater ecosystems provide many other highly valued and critical ecological services, and they support a very high diversity of species and taxonomic groups considering their relatively small volumes and surface areas.

Human impact has caused numerous stream reaches and shallow lakes to disappear, disturbed and polluted many others, and disrupted the close contact between the floodplain and the streams. Consequently, the diversity and abundance of numerous freshwater species have declined due to the profound restriction of areal cover and habitat diversity of freshwater environments. Moreover, the systematic loss of pristine, unpolluted freshwaters has threatened or eradicated those species that require such environments.

The overall disruption of the linkage between freshwater and terrestrial environments has far-reaching consequences for global hydrology, elemental cycling, and biodiversity. Among those consequences are enhanced risks of flooding and drought, greater risks of land erosion and marine siltation, and reduced opportunities for the countless plants and animals living a natural double life between freshwater and land to survive in the future.

Accompanying all of this disturbance and pollution has been the accidental or deliberate introduction of non-native organisms such as crayfish, plants, sport fish, and zebra mussels, which may monopolize freshwater habitats and drive the native, endemic species in formerly undisturbed lakes and

river systems to extinction. Several species of freshwater fish have gone extinct during the past few centuries, and many additional species of plants, large invertebrates, fish, and frogs now exist in extremely small and geographically isolated populations. These species face a great risk of extinction, and they can no longer provide their accustomed ecosystem functions. Nor can these species be enjoyed within most of their native area. Unfortunately, they will find it exceedingly difficult to recolonize newly restored aquatic habitat and contribute to future speciation.

Glossary

Convention on biological diversity The Convention was first enacted in June 1992, has been signed by many countries, and its objectives are the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding.

Functional type A group of species that share morphological and physiological characteristics that result in a common ecological role.

Global biodiversity assessment (GBA) The Global Biodiversity Assessment is an independent peer-reviewed analysis of the biological and social aspects of biodiversity

commissioned by United Nations Environment Programme.

Niche complementarity Refers to how the ecological niches of species may not fully overlap and complement each other. Consequently, an increase in the number of species that complement each other may result in a larger volume of total resources utilized and in higher rate of ecosystem processes.

Sampling effect Refers to the phenomenon where increases in the number of species increase the probability of including in the community a species with a strong ecosystem effect (Huston, 1997). This phenomenon yields an increase in ecosystem processes with increases in diversity without invoking niche complementarity. See Functional Diversity chapter (00061) in this work for ways of distinguishing between niche complementarity and sampling effect.

Extent of Grasslands

Grasslands are one of the major vegetation types in the world accounting for almost 40% of terrestrial surface (Shantz, 1954). They exist in all continents and cover a vast area of 49×10^6 km². In North America, grassland is the potential natural vegetation of most of the Great Plains and it reaches from the Chihuahuan desert in the south to the deciduous forests of Canada in the north, and from the Rocky Mountains in the west to the deciduous forest of the eastern United States (Figure 1). In South America, grassland is the potential vegetation of the vast pampas and most of the Patagonian steppe. Finally, in Asia, grassland ecosystems cover a huge area from Ukraine to China.

Determinants of Grasslands

Grasslands are water-limited ecosystems, and water availability defines their distribution in space. The amount of water available for plants primarily depends on precipitation amount and temperature. The former is the input of water and

the latter controls the loss of water from the ecosystem, since as temperature increases so does the evaporative demand. Increases in temperature result in increases in soil evaporation and plant transpiration; consequently, for a similar precipitation regime, the water balance becomes more negative as temperature increases. In contrast with most biological phenomena, primary production in grasslands decreases with increasing temperature, highlighting the importance of the indirect mechanism of the temperature control on the distribution of grasslands (Epstein *et al.*, 1996).

Grassland ecosystems occur in areas of the world that have an annual precipitation between 150 and 1200 mm and mean annual temperature between 0 and 25 °C (Whittaker, 1975). Along precipitation gradients grasslands are located between forests and deserts. In North America, South America and Asia, clear E–W precipitation gradients exist. In North and South America there are very small changes in elevation along those precipitation gradients and vegetation changes are mostly accounted for by precipitation. At the eastern and wettest end, Tall-grass Prairie is the dominant vegetation, which is replaced by Mixed-grass Prairie and by Shortgrass Steppe at the driest end of the gradient. A similar pattern occurs in Asia and South America (Figure 1).

Figure 1 Map of the global distribution of temperate grasslands. Adapted from Figure 7.2 in Bailey RG (1998) *Ecoregions: The Ecosystems Geography of the Oceans and Continents*, 87 pp. New York: Springer.

Although temperature and precipitation are the major determinants of the distribution of grasslands, fire also may play an important role. Fire becomes particularly important in the grass-forest ecotones where the dominance of grasses or woody plants in many cases is determined by the frequency and intensity of fires. For example, in North American Tall-grass Prairie, the area covered by woody plants has increased dramatically in the past 100 years and the human intervention in reducing fire frequency is largely responsible for the change (Briggs *et al.*, 1998). Similarly, data from pollen profiles, tree ring analysis, and photographic sources documented a shift in the grassland-forest ecotone in northern Patagonia with woody vegetation invading grasslands (Veblen and Markgraf, 1988). Again, fire control implemented by land managers was responsible for the forest expansion.

Soil texture also modulates the distribution of grasslands by modifying the soil water-holding capacity and the location of water in the profile. First, water penetrates deeper into the soil profile in coarse-textured soils than in fine-textured soils because soil water-holding-capacity depends on soil texture and is lower in the former. Therefore, the same rainfall event would penetrate deeper in a coarse than in a fine textured soil. Second, grasses and woody vegetation have contrasting rooting patterns with grasses having predominantly shallow roots and shrubs and woody plants having deep roots (Jackson *et al.*, 1996). Consequently, for a given amount of precipitation, grasses dominate in areas with predominantly fine-textured soils (Sala *et al.*, 1997) (Figure 2). Finally, seasonality of precipitation and the synchrony between the wet and warm seasons also affect the dominance of grasses and woody vegetation. Locations where precipitation occurs during the cold season, when evapotranspiration is low, result in a deeper distribution of water in the soil profile and these locations would benefit woody vegetation over grasses (Figure 2). In synthesis, precipitation and temperature are the major drivers

Figure 2 A conceptual model explaining the relative abundance of grasses and woody vegetation as a function seasonality of temperature and precipitation (congruence of warm and wet seasons) and soil texture. The gray shaded area represents conditions that are likely to favor the persistence of grasses, while the speckled area represents conditions that favor woody vegetation. The intersection of the two areas represents points where biotic influences are likely to be most pronounced. Adapted from Sala OE, Lauenroth WK, and Golluscio RA (1997) Plant functional types in temperate semi-arid regions. In: Smith TM, Shugart HH, and Woodward FI (eds.) *Plant Functional Types*, pp. 217–233. Cambridge: Cambridge University Press.

of the distribution of grasslands with their distribution modified at the edges by fire, soil and seasonality of precipitation.

This article focuses exclusively on climatically determined grasslands, in contrast with grasslands resulting from human intervention. Anthropogenic grasslands are located in areas where potential natural vegetation is forest. Humans, in an

attempt to produce forage for domestic animals, have logged forests and have maintained these plots as grasslands by mowing them periodically.

Biodiversity

Biodiversity can be examined in many different ways, and multiple definitions exist for what constitutes “biodiversity.” Nevertheless, the authors of the Global Biodiversity Assessment, using definitions originally proposed by the Convention on Biological Diversity, defined biological diversity as “variability among living organisms from all sources” (Heywood and Baste, 1995). Here, we focus on biodiversity in terms of taxonomically defined species, and the vast majority of studies quantifying ecosystem variation have used this measure. However, genetic biodiversity (genetic variation within a single species) and ecological diversity (including landscape diversity and functional group diversity) are also important components of biological diversity. The definition of biodiversity, therefore, will depend to a certain extent on one’s objective and scale of interest, ranging from the gene to the ecosystem.

Plant Species Diversity

Floristic diversity in grasslands varies broadly, with many natural types of grassland having a very high level of plant species diversity, at times approaching that seen in mainland tropical forests (Groombridge and Jenkins, 2002). Grasslands are dominated by grasses (family Gramineae excluding bamboos). The Pampa region in Argentina represents some of the highest diversity grassland, with more than 400 species of grasses (Cabrerá, 1970). In North America, more than 250 native species are found in Tallgrass Prairie (Freeman, 1998), the vast majority of which are perennial grasses.

Plant species diversity shows a great spatial variation. Grassland communities can be very species rich at fine spatial scales but tend to be similar and structurally simple over large areas (Groombridge and Jenkins, 2002). For example, plant species turnover among stands occupying different landscape position was 50% greater than among communities encompassing two degrees of latitude in the Flooding Pampa grasslands of Argentina (Perelman *et al.*, 2001). Grasslands tend to have low rates of endemisms, however, the climatic and soil gradients within them have led to substantial ecotypic variation and high genetic diversity (Groombridge and Jenkins, 2002). Plant species of grasslands can be categorized into four functional types: grasses, shrubs, succulents, and herbs (Sala *et al.*, 1997). The classification of plant species into functional types only has epistemological value and serves the purpose of facilitating the study of grasslands. This classification can be divided into many new subcategories or aggregated into fewer units depending on the needs of the analysis.

Grassland plant species can also be classified according to their photosynthetic pathway into C_3 and C_4 species. The two groups of species have differences in the physiology of photosynthesis and in the morphology of leaves that result in different ecological characteristics that separate them in time and space. Regional analyses of the distribution of these two types of grass species showed that C_3 species decrease

southward in North America and northward in South America and C_4 species show the opposite pattern (Paruelo *et al.*, 1998). Similarly, the abundance of C_3 species increases whereas that of C_4 decreases along an altitudinal gradient (Cavagnaro, 1988). These biogeographical analyses correlate with ecophysiological studies showing that C_4 species have photosynthesis optima at higher temperature, have higher water use efficiency, and are better adapted to low water availability conditions (Kemp and Williams, 1980).

Animal Species Diversity

All major taxonomic groups are represented in grasslands, but despite their large areal extent (40% of the area of terrestrial ecosystems), overall faunal diversity is lower than in many other biomes. The number of bird and mammalian species that are found primarily in grasslands are estimated to be 477 and 245, respectively, representing only 5% of the world’s species for each taxonomic group (Groombridge, 1992). Local diversity can be high in specific areas, for example, there are an estimated 208 avian species for Tallgrass Prairie (Kauffman *et al.*, 1998). However, general patterns show lower diversity for most taxonomic groups compared with other ecosystems.

One of the striking features of grasslands in terms of animal diversity is the presence of large herbivores as a prominent component of secondary production. These large grazing mammals have an important impact on the functioning of grasslands, altering patterns of nutrient cycling, primary production, and plant species composition (McNaughton, 1993), although their presence and diversity varies across different continents. For example, in the Great Plains of North America, nearly all the large grazing mammals went extinct during the glaciation of the Pleistocene, but the proliferation of a very few species, particularly *Bison bison* (plains bison), dominated the plant-herbivore interactions until the introduction of domestic cattle at the beginning of the twentieth century (Lauenroth and Milchunas, 1992). In contrast, African grasslands contain a very high level of mammalian diversity of grazers, with up to 20 species coexisting in a single reserve (Cumming, 1982). Finally, many South American grasslands evolved without the presence of large grazers, and their primary herbivory prior to the introduction of sheep and cattle was due to insect species (Bucher, 1982). Thus, although there is variation in the diversity of the large herbivores, their presence and importance is a distinctive characteristic of grassland ecosystems.

Small mammals, birds, reptiles, amphibians, and insects also play an important role in the functioning of grasslands. Species richness of small mammals is actually higher than that for large mammals (168 vs. 77 species overall), and they are mostly granivores or omnivores (Groombridge, 1992). In contrast, in Australian deserts small mammals are mostly insectivorous. Fluctuations in seed supply caused by unpredictable environmental conditions and the infertile soils could be an explanation for these differences (Morton, 1993).

Avian diversity in grasslands represents 5% of the total species of the world species diversity, and again the fluctuating

climate has an important control on this distribution. In this case, birds can migrate to remote areas outside of the grassland biome to seek alternative resources in periods of unfavorable conditions. In North American grasslands, which have a strong seasonality, there are large annual variations of passerines in response to climatic conditions. Additionally, within the grassland ecosystems, there exists a gradient of avian biomass that decreases with precipitation and primary production from the Tallgrass Prairie to the Mixed Prairie and Shortgrass Steppe (Lauenroth and Milchunas, 1992).

Reptiles in grasslands are less diverse than mammals and birds, and amphibians are less diverse than reptiles in the Tallgrass Prairie of North America (Kauffman *et al.*, 1998). Latitude has an effect on the biodiversity of reptiles and amphibians because they are ectothermic organisms, with an increase in the number of species from north to south of the Tallgrass Prairie (Kucera, 1992).

Insects are a diverse element of the terrestrial macrofauna of Tallgrass Prairie (Kauffman *et al.*, 1998), reflecting general patterns of diversity for terrestrial ecosystems in which insects represent more than 50% of the species (Strong *et al.*, 1984). They have a very important role as herbivores, pollinators, predators, parasitoids, and decomposers. Herbivorous insects are probably the most conspicuous functional group in Tallgrass Prairie (Kauffman *et al.*, 1998) and may replace large grazing mammals as the primary consumer in some South American grasslands (McNaughton *et al.*, 1993). Arthropods, constituting the largest proportion of invertebrates in the Shortgrass Steppe and primarily herbivores, take advantage of the large amount of belowground primary production (Lauenroth and Milchunas, 1992). In fact, most grassland invertebrate biomass is found within the soil and may be in the order of 100 to 1000 times as great as vertebrate biomass (Groombridge and Jenkins, 2002). In terms of species numbers, a soil invertebrate study in Tallgrass Prairie showed more than 200 species of nematodes, with fungivores constituting 40% of the nematode species (Ransom *et al.*, 1998) and the nematode biomass was exceeded only by that of bacterial and fungal groups.

Soil Microbial Diversity

Microorganisms are broadly defined as a group of microscopic life forms that include bacteria, archaea, viruses and unicellular eukaryotes like some fungi and protists. The diversity of microorganisms is known in much less detail than that of plants and animals but it constitutes a very important component of the soil biota (van der Heijden *et al.*, 2008). The large biomass of roots and other underground organs in grasslands and the high concentration of organic matter provide substrate for a large variety of microorganisms. The number of prokaryotes (bacteria and archaea) in grassland soils is estimated to be 32×10^{27} cells (Whitman *et al.*, 1998). Soil microbes represent a very diverse group of organisms in grasslands soils with a variety of functional roles. For the Shortgrass Steppe, the relative importance in terms of biomass of the different functional groups is bacteria > fungi > nematodes > protozoa > macroarthropods > microarthropods (Lauenroth and Milchunas, 1992).

There is a tight association between soil microbial communities and plant species composition (Wardle *et al.*, 2004). For example, arbuscular mycorrhizal (AM) fungi are obligate root symbionts that are present in most terrestrial ecosystems and have roles in plant mineral nutrition, carbon cycling, and biotic interactions. The number of AM fungal taxa per host plant species is high in grasslands (8.3 fungal taxa per plant species) only higher in tropical forests (18.2 fungal taxa per plant species) (Opik *et al.*, 2006). Also, AM fungal communities greatly differed in their composition in grassland ecosystems. In addition, bacteria and fungi communities differed in soils associated with plant functional types in grasslands. In the Great Plains of North America, the bacterial community that occurred under the mesquite shrub harbored greater levels of richness than those occurring beneath a C₃ perennial grass, a C₄ midgrass or a C₄ shortgrass communities (Hollister *et al.*, 2010).

Biodiversity and Ecosystem Functioning in Grasslands

The relationship between biological diversity and the functioning of ecosystems has been central in ecology and grassland ecosystems have been crucial in testing those ideas. The biodiversity and ecosystem functioning hypothesis indicates that the rate of ecosystem processes, such as primary productivity or nutrient cycling, might increase linearly as species richness increases and that this relationship eventually saturates as ecological niches overlap increases (Vitousek and Hooper, 1993). The increase in ecosystem functioning can be interpreted as an evidence of niche complementarity; that is, the higher the number of species with niches that do not overlap the larger the total volume of resources exploited (Tilman *et al.*, 1997). For example, plots containing just shallow-rooted or deep-rooted species should have lower productivity than plots containing both groups of species that jointly have access to water and nutrients stored in both upper and lower layers of the soil. Alternatively, the same results can be interpreted as resulting from the sampling effect, which results from the increased probability of including species that outperform the others as the number of species in the mix increases (Huston, 1997; Tilman *et al.*, 1997).

Grassland ecosystems played a key role in testing the biodiversity-ecosystem-functioning hypothesis mostly because of the small size and short life span of grasses that made manipulative experiments feasible with few resources and in short periods of time. The most common manipulative experiment type that was used in grasslands is called "replacement series" where, at the beginning of the experiment, treatments differ in the number of species but keep plant biomass or density constant. This type of experiment normally includes treatments where each individual species grows alone. Monocultures are used to estimate biodiversity effect, that is the difference in production between full diversity and monoculture treatments (de Wit and van den Bergh, 1965; Loreau and Hector, 2001). The Relative Yield Total (RYT) compares the performance of a mixture of species with the average of monocultures and indicates the strength of the biodiversity effect (de Wit and van den Bergh, 1965). Values

greater than 1 indicate that biodiversity is responsible for the increase in primary production.

The first large-scale field experiment was located in the North American Tallgrass Prairie and showed a saturating curve with total plant cover and nutrient uptake increasing with species richness up to a level of approximately 10 species (Tilman *et al.*, 1996). Other sets of experiments across Europe and USA basically showed similar results (i.e., Hector *et al.*, 1999; Reich *et al.*, 2004; Roscher *et al.*, 2005). Grassland biodiversity–ecosystem–functioning studies yielded an average RYT of 1.2 with a range between 0.9 and 2.2 (Figure 3) (Flombaum and Sala, 2008). The only experiment performed in a natural ecosystem had an RYT significantly higher than all the rest of the experiments that were done using synthetic communities. This result reaffirms the role of biodiversity on ecosystem functioning in grasslands and suggests that the effect of biodiversity on ecosystem functioning might be even larger than previously thought. Consequently, expected global biodiversity loss (see The Future of Biodiversity in Grasslands) will have a large negative effect on grasslands primary production and carbon sequestration. It is likely that the magnitude of the biodiversity effect would be positively related to the co-evolutionary history of species in the mix and negatively to the frequency and intensity of disturbance (Sala, 2001), both characteristics would argue for a larger biodiversity effect in natural than in synthetic communities. The effect of the loss of biodiversity in grasslands and its effects on the C cycle would be an example of the synergism of global change drivers where biodiversity loss would constrain grassland ability to cope with the effect of other stressors such as climate change and ozone pollution.

Figure 3 The effect of biodiversity on primary production in natural and artificial ecosystems. The RYT compares the performance of a mixture of species with the average of monocultures. Values greater than 1 indicate that biodiversity is responsible for the increase in primary production. The effect of biodiversity in natural ecosystem is larger than expected using artificial ecosystems. Reproduced from Flombaum P and Sala OE (2008) Higher effect of plant species diversity on productivity in natural than artificial ecosystems. *Proceedings of the National Academy of Sciences of the USA* 105: 6087–6090.

A large effort has been made in identifying the relative contribution of niche complementarity and sampling effect. Using analytical tools, Loreau and Hector (2001) found that niche complementarity was the most important mechanism to account for increases in primary production with biodiversity. Long-term field experiments in grasslands further strengthened this argument by showing that the niche complementarity increased while sampling effect decreased (Fargione *et al.*, 2007; van Ruijven and Berendse, 2009). After more than a decade of the first experiments performed in grasslands, a general consensus exists that plant diversity has a linear and positive relationship with net primary production, and that relationship is mostly due to niche complementarity (Hillebrand and Matthiessen, 2009; Hooper *et al.*, 2005).

The Future of Biodiversity in Grasslands

Biodiversity in grassland ecosystems is seriously threatened by human activity. Two independent studies that developed global scenarios of biodiversity change for the next 50 and 100 years highlighted that grassland ecosystems were among the most vulnerable ecosystem types (Sala *et al.*, 2000, 2005). Depending on how interactions among drivers of biodiversity loss were modeled, grasslands ranged from the most threatened biome to the third most threatened behind tropical forests, arctic ecosystems, and southern temperate forests (Sala *et al.*, 2000). According to the most comprehensive regional scenarios, grasslands may lose between 8% and 10% of the vascular plant species by the year 2050 (Figure 4 and Sala *et al.*, 2005). Differences between these estimates are driven by different socio-economic scenarios with Order from Strength being the most pessimistic from the biodiversity point of view with 10% loss and Adapting Mosaic the most optimistic with 8% loss. Order from Strength is a scenario driven by security and protection issues that yield a fragmented world with islands of wealth isolated from the rest of the world where population growth and food demand remain highest (Figure 4a). High demand for food and low technology transfer from developed to developing nations result in large conversions of grasslands into croplands with the corresponding loss in biodiversity. In contrast, Adapting Mosaic is one of the most optimistic scenarios from the point of view of biodiversity loss where regional watershed-scale ecosystems are the focus of political and economic activity (Figure 4b). Local institutions are strengthened and societies develop a strong proactive approach to the management of ecosystems. Perhaps, the most striking feature of these scenario results is the small difference between the most optimistic and the most pessimistic scenarios. Even under the most optimistic scenario, large biodiversity losses are going to occur in grassland ecosystems.

What makes biodiversity in grassland ecosystems so vulnerable to human impact? Are grassland ecosystems particularly sensitive? Or, are they located in areas that will be affected the most? Grasslands are located in parts of the world where ecosystems are going to be hit the hardest by human activity (Sala *et al.*, 2000, 2005). Grasslands are among the biomes that are going to experience the largest conversion in land use because of their mild climate and favorable soil conditions that made them quite suitable for agriculture. The

Figure 4 Scenarios of biodiversity change for different biomes for the years 2020 and 2050. Bars represent relative losses of biodiversity of vascular plants through habitat loss for different biomes for two scenarios: (a) Order from Strength and (b) Adapting Mosaic. Losses of biodiversity would occur when populations reach equilibrium with habitat available in 2050 and are relative to 1970 values. Darker bars represent scenarios for 2020 and lighter bars for 2050. Adapted from original Figure 10.6 in Sala OE, van Vuuren D, Pereira H, *et al.* (2005) Biodiversity across scenarios. In: Carpenter SR, Pingali PL, Bennett EM, and Zure KM (eds.) *Ecosystems and Human Well-Being: Scenarios*, pp. 375–408. Washington, DC: Island Press.

most dramatic changes in land use in grasslands are those that result from conversion into croplands. The conversion into agricultural land is not expected to be even across the world but driven by patterns of food demand and population growth that indeed are quite idiosyncratic. For example, the IMAGE2 model (Alcamo, 1994) predicts for the year 2100 a large increase in agricultural area in Africa and a reduction in North America resulting from both an increase in demand and an increase in intensification respectively. Biodiversity losses resulting from conversion to agriculture in one part of the world are not offset by a similar area that will be abandoned and is now reverting to grassland but that is located in a different part of the world. Therefore, total change in grassland area underestimates the impact of land-use change on biodiversity.

The major driver of biodiversity loss in grasslands in the next 50–100 years will be land-use change followed by climate change (Sala *et al.*, 2000, 2005). The third driver of biodiversity change in grasslands will be nitrogen deposition. Densely human-populated regions where nitrogen deposition is the highest are predominantly located in temperate regions where the potential native vegetation is that of grasslands.

Glossary

Community An ecological term referring to a set of species that occur in the same location that have the potential to affect each other either directly or indirectly.

Community structure The web of potential biological interactions among members of a community that may be characterized in terms of diversity, complexity, hierarchy, and stability.

Ecotone A zone of transition between two different habitats that may contain a community of organisms distinct from either habitat.

Habitat structure Analogous to community structure, but limited to the physical structural aspects of a habitat. The structure of habitats may be characterized by such measures as complexity, heterogeneity, regularity, stratification, and fractal dimensionality.

Microhabitat Locations within a habitat where organisms may carry out important aspects of their lives, such as places for harvesting food, nesting, or taking shelter.

Niche overlap The proportion of available resources that are shared by two species. Usually used in the context of a single resource that limits population growth.

Contrasting the Habitat with the Niche

As is the case with many ecological concepts, defining habitats and niches concisely and unambiguously is difficult. Habitat definitions are particularly prone to problems of scale. At the larger end of the scale is the biogeographical term *biome*. Some biomes may be considered the habitat of larger, well-traveled species such as large birds of prey, but usually the habitat is defined more narrowly. On the smaller end of the scale, the term *microhabitat* is used to describe the places where an organism spends part of its time. For instance, a fish may forage in the microhabitat that occurs near the banks of a river. Thus the concept of the habitat lies somewhere in between the biome and the microhabitat.

An ecological community is a suite of species that occur in the same location that at least have the potential to interact and affect each other either directly or indirectly. These effects are usually measured in terms of population growth or changes in the density of individuals. Different communities of organisms will generally reside in different habitats. If most species in one community have little chance of affecting the populations of other species in a different community, then these communities probably occur in different habitats. In this way, microhabitats refer to places within a community, and biomes encompass a number of different habitat types. Definition of habitat and community boundaries will depend on the exact species under consideration. For instance, it may be reasonable to distinguish the small mammal communities of

grassland from nearby riparian forest, though an individual jaguar may prey on species in both habitats.

The habitat concept was originally applied to single species, but because many species share similar habitats, some general habitat descriptions are applied to many species. Habitat descriptions used in this fashion often incorporate the dominant species commonly found in that habitat. In nature, borders between different kinds of habitats are often not very distinct. Generally, one habitat type will gradually give way to another creating a zone of transition. Communities in the transition zone may be qualitatively different from communities that occur within one habitat type or another.

The primary habitat preferences of a species can be displayed graphically. Ordination is the process of characterizing a species with regard to habitat gradients. Gradients can be displayed as axes on a graph. Usually, some measure of density or population growth is plotted, and the portion of the gradient that is occupied by the species is referred to as the habitat breadth of the species. **Figure 1** shows how two species of plankton can be compared according to a single habitat dimension, depth in the water column. There are potentially limitless gradients or factors that may be involved in characterizing the habitat of a species. Graphical representation of more than three variables in a single graph is difficult, but the concept easily extends into multiple dimensions.

The niche is a more abstract term than the habitat. It encompasses all possible interactions that a species has with the environment and other species in the community.

Figure 1 Two hypothetical species of plankton compared along the habitat axis of depth in the water column (top panel). This single habitat axis is correlated with two different niche axes, temperature and illumination. Species B is found in shallower, brighter, and warmer areas.

Conceptually, the niche is richer than the habitat and forms the foundation for much ecological theory. Because of the abstract nature of the concept, the definition is perhaps even more difficult to formulate for all species. There are striking similarities in the way niches and habitats are displayed. Like a habitat, a niche is often defined by axes, and there are multiple axes that can be compared.

The most common type of axes used to characterize a niche include those that define environmental tolerances and resource requirements. Humidity, sunlight, temperature, wind exposure, and pH are examples of environmental axes that help to define a niche. Resource axes may include food resources (insects, seeds, bacteria, nutrients), space requirements (breeding sites, refuges, foraging zones). **Figure 1** also compares the two plankton species in two niche dimensions, illumination and temperature, which are correlated with the habitat axis, depth. This highlights the similarity of habitat and niche axes, which are often difficult to distinguish clearly.

In practice, ecologists focus on a subset of niche dimensions that are the most important in determining the role of a species in the community. Among these are food resources that are essential for survival. These factors *limit* the population size of the species and therefore determine the distribution and abundance of the population.

In spite of the more limited role of the habitat in theory, the physical nature of habitat axes make them useful tools for practical purposes. Habitats can often be adequately described with relatively few variables, whereas to fully document the niche of a species requires careful study and a great deal of time. Yet if the habitat can be accurately captured, it is likely that many of the complex niche requirements and interconnections will be contained within the same habitat. As stated earlier, communities tend to map one to one onto habitats. The utility of this relationship is exploited for

management when there is insufficient time to study all aspects of an organism's ecology before an action needs to be taken. To preserve a single species, one must also preserve its niche requirements and the complex interconnections with the rest of the community. Preserving adequate habitat will often achieve this goal. This principle is important not only for managing target species, but for preserving and restoring biodiversity in general.

The primary habitat and niche for a number of species is given in **Table 1**. These brief characterizations are typically used as a shorthand way to describe where to find species and the basic role played by each in the community. Habitat descriptions include geographical information and often refer to the dominant species present (e.g., grassland, coral reef). Niche descriptions for a species usually begin with the main food items consumed.

As one moves through this list of very diverse species, the differences in the scales and roles are readily apparent. Trees may define different successional stages of a forest, each of which may be considered a different habitat. A jaguar may routinely cross into different successional stages on a daily basis, making it difficult to clearly define a jaguar's habitat. In contrast, certain trees, birds, and lichen are limited to only a certain successional stage, while specialized insects, parasites, and pathogens may even be limited to a single species of host. These differences make broad comparisons of niches and habitats difficult, but at any single scale, these concepts can be applied to facilitate meaningful comparisons among similar species.

History of the Habitat and the Niche

Niche Origins

It is tempting to think of a niche as a physical place. This is the common usage of the word, and there are examples in the early ecological literature that use the term *niche* in the purely physical sense. However the origins of the ecological niche reside in the more general observation that no two species are exactly alike.

Many naturalists in the latter part of the 19th century turned their attention toward documenting the traits that distinguish one species from another. When two species appeared very similar, it was thought that eventually differences could be found that would distinguish the unique role of each in the community. This idea was evident even in the writings of Darwin, and over time it has evolved into a very general principle: the principle of competitive exclusion. Exploring the implications of this relatively simple notion has dominated the study of ecology for much of the 20th century.

The principle of competitive exclusion and the concept of the niche developed in parallel through the early 1900s. Theoretical work by **Volterra (1926)** showed that if certain assumptions are met, only one species should be able to survive on a single resource. **Gause (1934)** demonstrated this principle experimentally with two species of *Paramecium* feeding on a common resource. Two species that consume the same resource in the same way simply cannot coexist.

Table 1 The primary habitat and major niche components of some representative species

<i>Species</i>	<i>Habitat/Biome</i>	<i>Niche</i>
California thrasher <i>Toxostoma redivivum</i>	Coastal chaparral; western North America	Generalist insectivore; territorial; sometimes a frugivore
Cuban crown giant lizard <i>Anolis equestris</i>	Tropical forest tree crowns; Caribbean (Cuba)	Generalist insectivore; short pursuit predator; territorial
Spotted salamander <i>Ambystoma maculatum</i>	Ephemeral ponds in deciduous forest; temperate North America	Generalist carnivore, breeds in ponds with few large fish
Jaguar <i>Panthera onca</i>	Tropical forests of all types, savanna; Central and South America	Small animal carnivore; solitary stalking predator, keystone predator
Plains zebra <i>Equus burchelli</i>	Tropical savanna, Africa	Grazer of short grass; gregarious; migratory
Harvester ant <i>Pogonomyrmex rugosus</i>	Sandy regions of deserts; southwest North America	Scavenger of small seeds; makes terrestrial, colonial burrows
Tawny mining bee <i>Andrena fulva</i>	Temperate fields, gardens; Europe	Nectar/pollen harvester; solitary soil burrower; pollinator
Camel cricket <i>Ceuthophilus silvestris</i>	Caves, moist environments; North America	Scavenger, detritivore
Ghost crab <i>Ocypode quadrata</i>	Sandy marine beaches; temperate and tropical Nearctic	Scavenger; territorial; nocturnal
Mussel <i>Mytilus californianus</i>	Intertidal, rocky marine shores; western temperate North America	Filter feeds on Plankton; sessile; pelagic larvae
Tardigrade (water bear) <i>Echiniscus spp.</i>	Moist film on plants, moss, or lichen; cosmopolitan	Plant and moss cell predator; meiofaunal (0.4-1.0 mm)
Guanacaste tree <i>Enterolobium cyclocarpum</i>	Tropical savanna, dry forest; Central America	Large canopy tree; pioneer, keystone species
Flowering dogwood <i>Cornus florida</i>	Temperate deciduous forest, North America	Shade-tolerant, understory; pollen and nectar producer
Deuteromycota fungi <i>Arthrotrichytrys spp.</i>	Moist soil, pools; cosmopolitan	Sit-and-wait predator of roundworms, hoop-snare structures
Slime mold <i>Acrasia spp.</i>	Moist soils, various habitats; cosmopolitan	Bacteria consumer, single and multicell stages
Schistosome <i>Schistosoma mansoni</i>	Humans and freshwater Snails; tropical, Africa, South America	Blood parasite in humans, gut Parasite in snails

The term niche was first used in the context of competitive exclusion by Grinnell, a superb naturalist of the North American west, as early as 1914. Grinnell's study of the California thrasher represents one of the first that specifically set out to characterize the ecological niche of a species, though he laid out the concepts of the niche and competitive exclusion 10 years earlier in a study on chickadees.

Grinnell's study of the California thrasher illustrates some of the most basic components of a niche (a) type of food consumed (mostly insects, berries at some times of the year), (b) microhabitat preference (beneath shrubby vegetation), (c) physical traits and behaviors used in gathering food (a long beak thrashed through the top layers of soil and leaves), and (d) resources required for shelter and breeding (dense shrubs for night roosting and nesting). These four basic factors allow

one to characterize the basic niche of most animals, and most animals differ with respect to one or more of these factors.

An analogous set of core niche dimensions may be constructed for plants, which tend to partition niche space along resource axes such as available light, soil moisture, and various soil nutrient gradients. Important niche dimensions for marine organisms may include temperature, substrate type, salinity, pH, and exposure to waves.

Thirteen years after Grinnell, the publication of Elton's *Animal Ecology* text (1927) established the term niche in the lexicon of ecology. However it was not until the work of Hutchinson (1957) that the concept of the niche was fully developed as a cornerstone of ecological theory. Hutchinson's niche is an n -dimensional hypervolume, implying that there are usually many factors, or dimensions, that define the role of

a species in a given habitat. These included yet extended well beyond the basic niche dimensions described by Grinnell.

Other ecological concepts emerged from this foundation. The resources that a species would use if it were isolated from all potential competitors is part of its fundamental niche. The realized niche is a subset of the fundamental niche that includes the resources actually consumed by the species in nature. The difference between the realized and fundamental niche can be attributed to competition from other species in the community.

Habitat Origins

Originally, the habitat of a species was not viewed as a part of its niche. In the early history of these terms they were treated separately. The habitat was seen more as a guide to the kind of community in which the organism played its role. For instance, the California thrasher occupies coastal chaparral of western North America, but this habitat description can be viewed as distinct from its niche within that habitat. Also, species were viewed as possessing suites of traits and physical tolerances that enabled them to be suitable only for specific habitats.

Over time, habitat axes were compared right alongside common niche axes, and the distinction became obscured. This change may be due in part to parallel development in the field of evolution and adaptation and increased knowledge of the processes involved. Today it is not difficult to imagine that two species may have evolved to occupy different habitats, whereas at a previous time only one species may have occupied both habitats.

The history of the habitat concept can also be traced back to the work of Grinnell and his contemporaries. In one of the earlier studies, Grinnell and Storer characterized the animals of Yosemite according to the elevations at which they occurred. In this mountainous region, species tend to be found in narrow elevational zones or bands.

At about the same time as the Yosemite study, Ramensky wrote that each species was unique and possessed adaptations that enabled it to tolerate a unique set of environmental conditions. This “principle of species individuality” bears strong resemblance to the early influences on the niche concept, except that in the habitat context, competitive exclusion was not at the core. Instead, species were seen to be adapted to certain conditions and habitats, and they independently sorted themselves out accordingly.

Subsequent work has confirmed that habitat boundaries are often determined by physical tolerances. However there are numerous examples where competition and other species interactions play an important role in determining the habitat breadth of a species in nature. This further illustrates how the habitat and the niche have converged over time. Therefore it is appropriate to treat the habitat and the associated gradients and axes as a subset of the niche.

Comparing Habitats and Niches

Multispecies Comparisons

The habitat and niche of any species can be characterized independently, but the true value of these concepts lies in comparing multiple species. The ability to display habitats and niches graphically greatly facilitates comparisons. **Figure 2** shows how species can be ordered along a habitat gradient. Copepod species show different patterns of abundance with respect to the gradient from ocean to land in the intertidal region. While in this instance there is a large amount of overlap, each species has a characteristic distribution in this region.

Habitat boundaries are rarely sharply defined. *Ecotone* is the term used to refer to this zone of transition between habitats. Because this zone is somewhat different from either neighboring habitat, an ecotone may contain several unique

Figure 2 The distribution of copepod species along the sandy intertidal habitat gradient in Massachusetts (only genus names are given). Reproduced from Pennak RW (1951) Comparative ecology of the interstitial fauna of fresh-water and marine beaches. *Ann. Biol. Sér.* 3: 462–463.

species. This concept was proposed to help explain distributions of species that did not appear to coincide with habitat boundaries. In a unique test of this idea, [Terborgh and Weske \(1975\)](#) found little evidence that subsets of bird species along an elevational gradient were responding to ecotones. Instead, it appeared that the elevational ranges of many species were independently defined by the presence of other closely related species. In this case, competition appeared to be more important than habitat gradients for setting the actual limits of species distributions.

The niche framework is typically used to compare groups of closely related species that consumed similar resources but differed in one or a few important ways. Suites of species in a community that utilize the same general resource were termed

guilds by [Root \(1967\)](#). Just as a guild of blacksmiths all work with iron yet have different specialties, assemblages of animals that specialize on seeds, fruits, or insects all have different ways of harvesting these resources.

Early studies focused on guilds that differed mainly with respect to body size. [Hutchinson \(1959\)](#) observed that species within a guild often differed by a minimum size ratio. Known as Hutchinsonian ratios, these regular arrangements of species body sizes occur in a number of vastly different communities consuming very different resources.

One example of the kind of pattern Hutchinson was attempting to explain is the assemblage of rodents that consume seeds in the deserts of North America. [Figure 3](#) shows how similar assemblages of rodents in different communities

Figure 3 A comparison of the niche relations among Great Basin and Sonoran desert rodent guilds. Different habitats support a different assemblage of rodents that show similar differences in body size. Reproduced from Brown JH (1975) *Geographical ecology of desert rodents*. In: Cody ML and Diamond JR (eds.) *Ecology and Evolution of Communities*, pp. 315–341. Cambridge: Harvard University Press.

contain a similar set of rodents. Each species differs from others in the same community mainly in terms of body size. Convergence is a term applied to organisms or communities that are not closely related historically that have members with similar physical features because they occupy similar niches. The implication is that parallel evolutionary trajectories were followed independently by different species because of similar selection pressures.

The underlying mechanisms that create such regular patterns can be explained because each species consumes resources of a size class that is proportional to its body size. Smaller rodents consume smaller seeds, while larger rodents eat larger seeds. In a different community, smaller fruit pigeons consume smaller fruits, while larger species primarily consume larger fruit. For a medium sized bird, small fruits take too long to gather and handle, and the bird can not eat them efficiently enough to sustain itself. Larger fruits may be too big to handle or crack open.

Many types of food resources such as seeds, fruit, or arthropods have a wide, flat distribution along a size gradient. These relationships can be displayed graphically with a single niche axis, food resource size (**Figure 4**). One curve represents the available resources, in this case seeds, and the narrower curves underneath represent the sizes and amounts of seeds consumed by each species. This division of available resources among members of a community is termed resource partitioning.

Utilization curves are often bell shaped (normal, Gaussian) to reflect the tapering ability of each species to consume seeds away from the "optimum" size. This type of niche representation allows direct comparison of the amount of overlap in resource consumption. If food is indeed the primary limiting resource, the overlap of species resource utilization curves directly represents the amount of competition that each species is experiencing. It is the regular spacing of curves to minimize overlap, or competition, that creates the pattern of regular size distributions of animals seen in natural communities. This simple framework forms the basis of niche theory.

The concepts of fundamental and realized niches can be clearly visualized within this framework of graphical representation of both habitat and niche dimensions. Mussels are capable of living in a wide range of elevations above the low tide mark, and they will move into these spaces in the absence of other species. However other animals, such as barnacles, are better adapted to occupy lower positions and can outcompete mussels in some zones. That is why in natural communities,

the realized niche of mussels in terms of this habitat gradient is usually narrower than the fundamental niche.

A similar process may be operating in the granivorous rodent example presented earlier. Each rodent may be capable of consuming a wider range of seeds, albeit inefficiently. In nature, either there are fewer of these suboptimal resources available because of competitors, or each species deliberately chooses a narrower range of seeds to consume to avoid competition.

The effect of competition on realized niches can be seen by comparing island and mainland communities. Islands usually support fewer species than equivalent mainland habitats. It has been shown for many kinds of species that in these species-poor island communities, species tend to eat a wider array of foods and therefore have wider niches. This agrees with the expectation based on niche theory outlined earlier: there are fewer potential competitors on islands, and therefore there is less resource overlap with other species acting to constrain their niches.

Species that have very high overlap in many niche dimensions often have little or no overlap in one key dimension. This principle, called niche complementarity, lies at the heart of the guild concept. In previous examples, similar species consumed the same general resource and had high niche overlap, but they showed little overlap with respect to a single dimension: body size. Typical niche axes where complementary species can be found include size, light (nocturnal/diurnal), benthic/pelagic, and canopy/ground or coniferous/deciduous microhabitat.

In many instances niche differences among species are clear, but sometimes niche differences are extremely subtle and require careful study to be revealed. For instance, five species of *Dendroica* warblers can all be found in the very same tree in temperate zone coniferous forest habitat. All glean similar types of prey, primarily lepidopteran larvae, from the surfaces of the tree. Only careful study by MacArthur (1958) revealed that each species favors different parts of the tree, and each tends to move about the tree in different ways (**Figure 5**). Thus it is not only the type of food resource that is limiting the population growth of each species, but where and how that food resource was harvested. There are enough subtle differences in microhabitat use and behavior to allow coexistence of species that at first glance appear to share equally the same limiting resource.

Niches can change through time. For instance, the larval forms of many organisms often have completely different niches from adult forms. Thus, the term ontogenetic niche has been applied to amphibians, arthropods, and a wide variety of marine organisms. The great versatility of the niche concept allows incorporation of these temporal changes by simply adding a temporal axis to the species niche. The realized niches of species in a community can also change through time if the community undergoes change. Extinctions and invasions cause rapid community changes that in turn result in niche shifts among other community members.

Niche theory is the branch of ecology that has taken these informal graphical models and extended them mathematically to model the process of competition and community organization. The origins of niche theory can be traced back to the early work of Volterra, and has grown and undergone dramatic

Figure 4 A hypothetical species assemblage. A nearly continuous spectrum of resources that differ mainly in size (top curve) are consumed and partitioned among different species that also differ mainly in size (A–D).

Figure 5 Niche relations among some North American warblers that forage in coniferous forests. Species differ according to microhabitat (parts of the tree most frequently visited) and foraging behavior. Reproduced from MacArthur RH (1958) Population ecology of some warblers of Northeastern coniferous forests. *Ecology* 34: 599–619.

changes. Complex interactions among members of a community are very difficult to measure, and the approach of studying theoretical models has greatly enhanced our knowledge of the factors that influence community dynamics.

Other Niche Dimensions

The classical context of niche comparisons is mainly restricted to niche axes characterizing habitat and food resources. Some ecologists have even considered the definition of a niche to be limited to the food resources consumed. However developments in the field of ecology through the 1900s have made it clear that an expanded definition of the niche that encompasses all the interactions of a species within a community is most appropriate. A broad definition of the niche includes all potential interactions that ultimately have the effect of changing the population density of another species in the community.

Mutualistic interactions are somewhat different from food resources in that they are often not literally consumed, nor are

they occupied as in a nesting or sheltering place. However in niche descriptions, mutualistic interactions are treated much the same as other resources in that they may be limiting and therefore may even be competed for. For instance, pollinators interact mutualistically with angiosperms, yet from the point of view of a plant, they may be regarded as any other resource.

Indirect Interactions

Competition for resources has historically played a central role in niche descriptions. More recently, studies have uncovered processes where two or more species coexist because of factors that have little to do with resource niche axes. For example, predation can act to promote coexistence of potentially competing species in the following way: The presence of a predator may reduce the numbers of one prey species and thereby allow other species that have similar resource requirements to coexist. If two or more species are all harvested by a predator that does not show preferences for any specific prey type, then the most common prey will experience a disproportionate amount of predation. In this way, the presence of a predator can actually promote coexistence of species and an increase in biodiversity. Predators that have this effect have been referred to as keystone species because of their disproportional affect on community diversity.

An excellent example of this process can be found in the rocky intertidal communities of the eastern Pacific. Paine (1980) and colleagues conducted a unique set of experiments demonstrating that the presence of a starfish predator (*Pisaster*) enabled the coexistence of a number of species, whereas in the absence of the starfish, the community was dominated by the California mussel. The niche description for a barnacle in this community would therefore be incomplete without incorporating information about not only the presence of the California mussel, but also the relative vulnerability of each of these species to starfish predation. This implies that the niche characterization may change depending on the presence of potential predators and prey and their specific traits.

Predation certainly can be seen as a direct interaction, but the example above falls into the class of indirect interactions. A keystone predator can enhance the abundance of a species by interacting with a third species. Many interactions may cause ripple effects through a community in indirect ways. Elephants change the physical structure of their habitats, and many species excavate holes and nests that are used by other species. Parasites and pathogens can also have indirect effects on entire communities.

Viruses and other pathogens may initially appear to occupy a very simple niche, especially those that are confined to live entirely inside the body of a host species. How can such an organism play an important role in the community through indirect interactions? Pathogens can significantly impact the population size of the host species. This change in abundance may have consequences for other species, such as predators and prey of the infected species.

Some pathogens have complex life cycles that depend on more than one host species, and sometimes these hosts are very different. For instance, in using humans and snails at different stages of its life cycle, Schistosomiasis provides a clear

link between humans and some snail species that are used as hosts for different stages of the life cycle.

Another interaction involving pathogens provides an example of apparent competition. One host species may be relatively unaffected by a pathogen, whereas other species may be severely impacted. In this case, the unaffected species can act as a carrier, spreading the pathogen to other species in the community that are more susceptible, causing their decline. On the surface, this pattern may resemble competition.

Community ecologists have used various methods to incorporate these indirect interactions into model representations of communities. It is certainly not as straightforward as simple resource utilization graphs. Mathematical matrices have been applied to study the dynamics of communities. In this format, all pairwise interactions can be explicitly considered, and broad concepts such as the relationship between community stability and complexity have been studied within this framework. Recently, web theory has been applied to this task because complex interactions within communities can be more explicitly constructed. All of these theoretical constructs of communities are based on the niche concept, thus the utility of the niche concept has grown even as the field of ecology has undergone dramatic changes.

Evolution of the Niche

Ecological studies can help us to understand *why* species occupy unique niches, but *how* did the great diversity of species arise in the first place? The processes underlying the evolution, adaptation, and coexistence of species that have unique niches is a fundamental aspect of understanding biodiversity.

For many organisms the primary mode of species formation, and therefore the primary generating force for biodiversity, is thought to involve differentiation of isolated populations. A terrestrial species may have populations separated by water, or coastal marine populations may be isolated by unsuitable open ocean. Over time, these populations undergo changes and begin to accumulate different characteristics. Some of these differences are due to chance events such as mutation and genetic drift. Traits change over time as the organisms adapt to the unique features of their respective habitats. Subtle environmental differences may result in the evolution of thicker shells in a population of crabs, or a preference for fish over mammals in a population of killer whales.

This differentiation by adaptation to different habitats with different food resources is in itself one engine for generating biodiversity, however it cannot explain the vast diversity of species that occur within a single habitat. Eventually, populations that have been isolated for a while may reestablish contact, and individuals will attempt to coexist within the same community. It is at this stage of speciation, referred to as secondary contact, that one can see how the concept of the niche is fundamentally related to species diversity.

When secondary contact occurs, one of three outcomes is possible. First, populations may interbreed, and speciation is not completed. Second, if populations do not interbreed, they may either coexist, or, third, one may outcompete the other. Which of these two latter outcomes is realized will depend on

the amount of niche overlap between these species. If overlap is high, then one species is likely to outcompete the other. If overlap is low enough, the species may coexist.

In situations where coexistence is possible (or at least extinction is not very rapid), and the species involved still possess similar traits, we would expect evolutionary changes to occur over time. Individuals that consume limiting resources that are shared with another species will experience more competition and may survive or reproduce less than individuals that do not overlap as much. If there is natural variation in resource consumption among individuals in each population, and if the traits that cause this variation are genetically passed to offspring, then the species are expected to diverge over time to minimize niche overlap. This process is called ecological character displacement, and it is a logical extension of the competitive exclusion principle into evolutionary time. **Figure 6** illustrates the process of character displacement. It is the change in a trait of a species, such as body size, that leads to a shift along a niche axis and reduction of overlap.

The empirical evidence for character displacement lies mostly in descriptive, snapshot-like comparisons of species. Typically, closely related communities are compared and character displacement is inferred if the presence or absence of one species is correlated with a change in the traits of another species. These studies infer that it is niche overlap in the use of a single limiting resource that has led to the observed species differences. **Lack (1947)** was one of the first to infer character displacement in this way in his study of Darwin's finches, **Figure 7**.

Static character differences constitute indirect evidence for competitive processes and have therefore received criticism. To document evolution directly in natural populations is a difficult task because even rapid evolutionary changes may require generations to occur. Nevertheless, there is solid empirical evidence for niche evolution in nature. The Grants and their colleagues (see **Grant, 1999**) have shown the niche of Darwin's finches evolved over time according to the seeds

Figure 6 A graphical representation of ecological character displacement. Initially upon secondary contact, species have highly overlapping resource utilization. Over time (b) resource overlap and competition is reduced through evolutionary changes that result in a shifting of the niche.

Figure 7 Size variation among three species of Darwin's finches (genus *Geospiza*) that specialize on seeds. Individuals are pooled among islands (given) to generate the histograms of beak depth. Populations on islands with fewer species (lower two panels) are intermediate in size compared to islands with the complete complement of species (upper panels). This is indirect evidence for ecological character displacement caused by competition for seeds; Pennsylvania in the United States. Reproduced from Grant PR and Schluter D (1984) Interspecific competition inferred from patterns of guild structure. In: Strong DS, Simberloff D, Abele LG, and Thistle AB (eds.) *Ecological Communities*, pp. 201–233. Princeton: Princeton University Press.

that are available. In unique experimental tests of character displacement, Schluter (1994) has shown that stickleback fish populations changed over time in response to competition and niche overlap. Natural selection acted against individuals with feeding anatomies that caused them to harvest resources that were shared between species.

Ecologists may differ in opinion about the importance of character displacement in specific instances, and there are surely other very important forces that act to shape community composition and species traits. Nevertheless, few would doubt that character displacement is an important fundamental process in shaping communities of organisms.

The Habitat and Biodiversity

We have traced the habitat concept from its independent origin through its incorporation into the concept of the niche. With growing awareness of the need to conserve biodiversity, the habitat concept has emerged again as an important tool for management. Essentially, habitats contain functioning

communities of organisms. If the goal is to protect a focal species, then setting aside appropriate habitat will likely result in preserving the required niche elements of the species as well.

Assessing appropriate habitat has two great advantages over attempting to define niches. First, because of the physical nature of habitats, they are easier to recognize and quantify. Second, ecological communities tend to fall along similar boundaries as habitats, thus by preserving a habitat one is more likely to preserve communities with all niche interconnections intact. This relationship among species, communities, and habitats has become the center of the more recent conservation efforts termed habitat conservation plans.

For example, in San Diego county, a number of endangered or threatened species rely on a unique type of habitat: chaparral, or coastal sage scrub. A major goal of habitat conservation plans in this region is to create contiguous regions of appropriate habitat. In this way, the needs of many species can be met at once.

Habitat fragmentation is a major concern because small refuges of habitat are essentially islands. Islands are prone to a number of processes that degrade biological diversity. Small populations on islands are prone to extinction through random fluctuations in numbers. The geometry of islands gives them a high ratio of edge to interior. Because animals may wander across this boundary, those that rely on the interior island habitat experience more competition and predation from those outside the island. More isolated islands are also less likely to be recolonized in the event that a population has gone extinct. Therefore, natural reserves and habitat conservation plans pay particularly close attention to fragmentation and try to consolidate larger parcels of unbroken natural habitat.

Once a habitat has been severely degraded, there may be ways to return it to its former natural state. Habitat restoration is a challenging field, but one that has made great strides recently. Wetlands have been restored by controlling of the water table and planting appropriate vegetation. Foresters have been restoring habitat for decades by replanting harvested areas. Highway construction projects aim to restore natural vegetation upon completion of a project by spraying a mix of grass, flower, and shrub seeds in a fertilizing matrix onto the bare ground. Another interesting example of habitat restoration can be seen with the construction of artificial reefs. By placing physical structures on the seafloor, a reef community can take hold and flourish. This is an example of how subtle environmental features such as physical structure can have a profound effect on habitat quality and species diversity.

Two general mechanisms act to promote species diversity within structurally diverse habitats. First, biological species diversity leads to more species diversity. A monoculture such as an orchard allows for relatively little niche differentiation of the organisms within. There is little opportunity for species to adapt to specific host species, and this applies to insects, birds, mammals, and parasites. Reduced numbers of species limits the number of possible niches in an orchard when compared to a tropical rain forest.

Artificial reefs belong to a second class of mechanisms that generate biodiversity by acting over and above the biological mechanisms. These are the purely physical features of the

habitat that allow for increased niche differentiation. Dead logs, snags, distinct ground, and shrub layers will provide habitat heterogeneity that allow higher trophic levels to differentiate. Just as warblers partition the physical space within a single tree species, other competitors that use different tactics to forage on similar prey can partition a structurally diverse habitat to a finer scale. Behavior plays a key role as foraging tactics and escape strategies of prey are honed to specific microhabitats within the larger forest. MacArthur and colleagues (1962) were among the first to correlate purely physical aspects of a habitat with species abundances. Since then, physical habitat structure has been shown to augment species diversity in systems as diverse as birds, lizards, stream invertebrates, fish in marine reefs, and microorganisms in beakers.

Keystone species have a disproportional effect on many other species in the environment, and as such are often the focus of conservation efforts. Starfish foraging in the intertidal zone have a positive effect on biodiversity. Jaguars prey on a number of small rodents and animals, and they tend to capture prey in proportion to their abundance. The net effect is to prevent any single species from becoming very common and outcompeting other prey species. The niche of the jaguar and the starfish includes this community-wide role, and they are sometimes referred to as keystone predators.

Management strategies have turned more attention toward keystone species in order to preserve communities. A similar keystone role is played by tree species such as the Guanacaste tree of Central America. In this instance the link between the niche, the habitat and biodiversity is clear. The Guanacaste tree is vital for establishing forest in grassland habitats, and it therefore plays a key role in restoring tropical dry forest. The niche of this species would include its role in developing habitat structure and therefore intersects with the niches of many other species in the community.

The habitat and the niche can interact synergistically with human activity to cause extinctions and loss of biodiversity. Niche complementarity has led to a very general pattern whereby species with similar niches are spatially segregated. Increased human movements on a global scale has had a dramatic effect in bringing these species into contact by introducing exotic species into new geographic regions. If these alien species have high niche overlap with resident species, the resident species can be driven to extinction by a successful invader. Even though there are many cases where introduced species can not establish or outcompete residents, many threatened and endangered species are at risk because of invaders. This threat also extends to introduced predators. Resident species that have adapted to a niche in one community can be driven to extinction by a predator that has evolved in a different community.

Conclusions and New Frontiers

The concepts of the habitat and the niche have grown mainly through study of the organisms most familiar to us as humans. Most conceptual advances were derived in some way from the study of larger animals and plants. Even within these groups, there has been a disproportionate amount of study of

birds. Yet there have been significant contributions from other sectors of the biological world. For instance, Gause's study of *Paramecium* lies at the heart of the niche concept. It is fitting then that more attention is returning toward understanding the niches of microorganisms.

Experimental evolution using bacteria is a growing field that holds great promise. The short generation times and relatively simple ecologies of bacteria enable evolutionary experiments on the scale of the community. This is one of the few instances where the interaction of ecological and evolutionary factors can be studied during the process of community formation.

There is an enormous number of microscopic, planktonic and meiofaunal (0.4–1 mm) organisms about which we know very little. These organisms are ubiquitous, speciose, and show an amazing amount of diversity in form. However there are significant obstacles encountered in studying these smaller organisms that even make it difficult to quantify the habitats in which they can be found. Practical problems arise while trying to observe them in nature, while on the other hand, many fail to survive the transfer to laboratory environments. Yet there are compelling reasons to learn more about their ecology.

The niche of a terrestrial vertebrate or marine invertebrate is often defined largely by how it feeds or defends itself. In turn, anatomical structures have evolved that reflect these niche differences. Similar examples can be found in the nearly invisible world of small creatures around us. For instance, ciliates and other protozoans possess anatomical structures that suggest a diversity of roles even greater than those observed in larger organisms, yet there has been comparatively little study of their niches in nature.

Some organisms stretch the concepts of the niche and habitat to their limit. Some plants display an extreme amount of what is referred to as phenotypic plasticity: different individuals develop extremely different body forms depending on the environmental circumstances. Some ciliates have the ability to radically change the form of feeding or defensive appendages even within the lifetime of an individual.

Many bacteria, and even some larger meiofauna like the bearlike tardigrades, can enter a sporelike state to withstand extreme environmental conditions. They may persist for long periods of time in this state and may be very difficult to detect. Much like the seed bank of desert plant communities, these alternative states pose difficult problems in understanding the dynamics of their communities.

The habitat and the niche have grown, developed, and been applied with great success. Observation and theory have played important roles throughout, and experimental investigation has undergone a resurgence. Yet it is intriguing to ponder that most of this development has included only a subset of the biological world. Only time will tell whether the concepts of the habitat and niche will persist as the complex interactions of these diverse communities of small creatures are revealed.

Glossary

Alpine life zone Life zone that occurs above the climatic high-elevation treeline or its bioclimatic equivalent.

Altiplano Extensive internally drained high-elevation plain found between the Western and Eastern Cordilleras of the Andes at 3800–4100 m above sea level.

Andes Mountain range comprised of various geological units that extends from latitude 12° N in Venezuela to 56° S off the southern tip of South America.

Endemism State of being unique to a defined geographic location, such as an island, nation or other defined zone, or habitat type.

Ma Millions of years.

Páramo High-elevation vegetation zone found from 11° N to 8° S in the South American Andes and on some mountains in Costa Rica and Panama.

Patagonia Region of South America in southern Argentina and Chile extending from the Río Colorado to the Straits of Magellan Fuego and from the Andes to the Atlantic Ocean and often considered to include northern parts of the Island of Tierra del Fuego.

Phylogeny The evolutionary history of a group of organisms or populations.

Southern Andean steppe High-elevation vegetation zone found from latitude 27° S to 56° S in the South American Andes, in Argentina, and Chile.

Introduction

The high-elevation habitats of the major mountain ranges of the world contain a sizable amount of plant biodiversity at local and global scales. Such habitats are intriguing in that most are of recent geological origin and are known to have garnered evolutionary lineages from many different biogeographic sources. Importantly, high-elevation areas provide critical ecosystem services such as the regulation of water flow and slope stability and, on account of their steep altitudinal gradients and opposite-facing slopes offer readily accessible thermal refuges for species affected by climate change. The high-elevation habitat, in addition to being of great scientific interest, thus is important for conservation as well as for the welfare of humanity.

In this article, the authors review plant biodiversity in the páramo, puna, and southern Andean steppe of the South American Andes. A wealth of other vegetation types (including tropical cloud and cool temperate forest, desert communities, scrubland, and grassland) subtend these three high elevation vegetation zones, but for reasons of space, these will not be considered here. The authors first situate Andean high elevation ecosystems in a global vegetation context. They then synthesize the uplift history and topological features of the Andes relevant to present-day biodiversity patterns. Having set the stage, the entire high-elevation flora, considering species richness, and endemism are overviewed, and recent findings on the origin of the flora as revealed by phylogenetic construction are highlighted. Finally, narrative accounts of the páramo, puna, and southern Andean steppe are provided.

High Elevation Habitats of the Andes

The South American Andes extend from latitude 12° N in Venezuela to 56° S in Chilean territory and as such constitute

the world's longest uninterrupted high-elevation mountain corridor (**Figure 1**). The Andes make their first appearance in the Lake Maracaibo region of Venezuela; their last terrestrial vestige is found on the Cape Horn Islands off the southern coast of Tierra del Fuego. Traditionally, there has been a tendency to divide the high-elevation habitat into páramo, puna, and southern Andean steppe (**Arroyo et al., 2010**). The páramo extends from 11° N in Venezuela to around 8° S in northern Peru (**Luteyn, 1999**) and is found entirely within tropical latitudes. The puna covers tropical to midtemperate latitudes, occurs from 8° S to roughly 27° S (**Luteyn and Churchill, 2000**; **Arroyo et al., 2010**; but see **Martínez Carretero, 1995**). Southern Andean steppe extends southward and lies entirely within temperate latitudes. Taken together, the páramo, puna, and southern Andean steppe are estimated to cover more than 913,600 km², the equivalent of approximately 5.1% of the land area of the South American continent (**Arroyo et al., 2010**). Páramo covers around 63,600 km², puna 684,400 km², and southern Andean steppe 165,600 km².

In the northern tropical and southern temperate Andes south of 35–37° S, a consistent treeline defines the lower limit of the high-elevation ecosystem. However, over large intervening areas of the Andes a treeline is often lacking, and here the high-elevation ecosystem transitions gradually into shrublands, grasslands, or desert communities. While the páramo, puna, and southern Andean steppe vegetation zones enclose South America's equivalent of alpine vegetation in their upper reaches, it is important to realize that these vegetation types can extend well below the equivalent of the alpine life zone, defined as that vegetation above the upper tree limit. Under the **Rivas-Martínez (1993)** bioclimatic system for defining vegetation zones the puna as defined in this article, based on work in northern Andes of Chile (**Luebert and Gajardo, 2000**) and southern Peru (**Galán de Mera et al., 2003**) is included mostly in the orotropical and crytropical bioclimatic belts. The páramos of Venezuela traverse the upper part of the mesotropical belt into the orotropical belt

Figure 1 Digital elevation model of South America showing the South American Andes. The inset shows the extent to páramo (PA), puna (PU), and southern Andean steppe (SA).

(Méndez, 2007). Under the Rivas-Martínez (2003) bioclimatic scheme, generally, northern hemisphere subalpine areas fall into the orotemperate belt, while alpine areas fall into the cryotemperate belt. The degree of the mismatch with the alpine life zone can be illustrated by considering Körner *et al.*'s (2011) recently proposed bioclimatic rules, which consider mean growing season temperature (GST) and length of the growing season (GS) for defining the major vegetation belts on mountains. Estimated GST (GS, approximately 2 months) at treeline for the far southern Andes close to Ushuaia (55° S) is 5.1 °C, and fits fairly well with Körner *et al.*'s (2011) bioclimatic definition of the lower alpine belt (GST < 6.4 °C to > 3.5 °C; GS of < 94 days to 54 days). However, in the drier central Chilean Andes (33° S), where the lower limit of southern Andes steppe lies immediately above an open *Kageneckia angustifolia* (Rosaceae) tree line at 2200 m (Cavieres *et al.*, 2000a), estimated GST (GS, approximately 4–5 months) calculated from Cavieres and Arroyo (1999) is still as high as 9.9 °C at 2600 m. Estimated GTS for some puna localities in Argentina and Chile is minimally 6.7–9.7 °C (Cabrera, 1968; Ruthsatz, 1974; Arroyo *et al.*, 1988), while for some páramo localities it oscillates around 8–10 °C (Cavieres *et al.*, 2000b; Rangel, 2000a). Based on this brief analysis, with the exception of those parts of the southern Andes where there is a good treeline, páramo, puna, and southern Andean steppe tend to overlap with Körner *et al.*'s (2011) montane belt (GS temperature of < 10 and > 6.4 °C).

The Physical Setting

To understand biodiversity patterns in the high Andes, a clear picture of the time of appearance of the high-elevation belt and of landscape evolution at different latitudes along the Andes over which clades have developed is essential. In this section, the authors focus on the main geological events and accompanying topological changes that led to the emergence

of high-elevation habitats, relying heavily on the comprehensive reviews by Orme (2007) and Young *et al.* (2007).

The Northern Andes, housing the relatively small area of páramo in comparison with puna and southern Andean steppe, form a distinctive tectonic realm combining continental crust deformation, accreted oceanic terranes, magmatism, and strike-slip faulting. They arise in Venezuela in the form of two southward-running parallel ranges on either side of Lake Maracaibo, where the highest peak is Pico Bolívar (5007 m). These ranges merge to become part of the Colombian Cordillera Oriental just inside the border with Colombia. Further south the Cordillera Oriental merges with the parallel ranges of the Cordillera Central and Cordillera Occidental in southernmost Colombia. The Andes in Ecuador are initially characterized by two large cordilleras separated by numerous interconnected intermontane valleys, which eventually become less well-defined southward on account of several deep valleys traversing the mountains. The highest peak is Volcán Chimborazo (6310 m). At the southern end of the páramo is found the Huancabamba Depression, thought by some authors (e.g., Molau, 1988) to comprise an important biogeographical barrier for north–south migration, although the alternate hypothesis that strong climatic differences, north and south of the depression, are responsible for floristic differences should also be considered. Under present climatic conditions and heights of the Andes the páramo is highly fragmented (Josse *et al.*, 2009) in comparison with the situation during the glacial cycles when the treeline became depressed by approximately 1500–2000 m (van der Hammen and Cleef, 1986). Postglacial conditions are thought to have favored the evolution of many local endemic species.

The huge extension of puna vegetation, the equivalent of over ten times the land area of páramo, develops mainly in the topographically complex Central Andes yet it shows far better physical continuity than the páramo habitat. There are two main cordilleras (Western and Eastern). In northern Peru, these cordilleras are poorly defined due to several deeply traversing valleys. The highest peak here is Huascarán (6768 m). Southward in northwest Bolivia, northern Chile

and northwest Argentina, the Western and Eastern Cordilleras are separated by the Altiplano, a wide (120–250 km), high elevation (3800–4100 m) plain. The present relief of the Central Andes is largely a result of late Cenozoic uplift, igneous activity, and erosional exhumation. The Western Cordillera is a late Cenozoic magmatic arc with many active volcanoes (e.g., Volcán Sajama, 6542 m), whereas the Eastern Cordillera is mostly comprised of Ordovician sediments intruded by granite batholiths, these supporting extinct volcanoes such as Illampu (6550 m) and Illimani (6457 m). The Altiplano, which lay at sea level until about 60 Ma, today contains approximately 10,000 m of Cenozoic continental deposits (Horton *et al.*, 2001). The high Altiplano is important in that it provides good continuity for the dispersal of organisms between the widely separated Western and Eastern Cordilleras. However, an area of severe aridity on the western flanks of the Andes at 24–25° S constitutes an important biogeographical barrier for north–south migration (Villagrán *et al.*, 1981; Arroyo *et al.*, 1988).

Southern Andean steppe covers close to three times the land area of páramo, and just under a quarter of that of puna. The tectonic history of the Southern Andes (including the Patagonian Andes) includes long periods of extension and basin formation during the Mesozoic and Oligocene–Miocene, alternating with relatively short intervals of mountain building/exhumation during the mid-Cretaceous and Late Miocene. In the northern extreme of southern Andean steppe the Andes are comprised of a principal chain of variable width. As a result of aridity, which slows the erosion–deposition cycle, the terrain is very steep. From 34° S south, there is a sharp decrease in the elevation of the main chain and a switch from V-shaped to U-shaped valleys coincident with a change from dominantly fluvial erosion in the north to dominantly glacial erosion in the south. From the Gulf of Penas (42 °C) southward, the Andes are subdivided into the lower Insular Patagonian Andes that run along the Pacific Ocean and the higher eastern Patagonian Andes (>3000 m). Further south, the Patagonian Andes lose elevation to rise to around 1500 m on the north coast of the Straits of Magellan. On the island of Tierra del Fuego the Andes are represented by the Cordillera de Darwin. There are many high peaks (including volcanoes) in the area of the Andes housing southern Andean steppe: to mention a few, from north to south: Mount Aconcagua (6962 m), Volcán Tinguiririca (4623 m), Cerro Tronador (3478 m), Mount San Valentín (4058 m), Cerro Paine Grande (3240 m), and Mount Darwin (2488 m). North of 38° S the higher elevation of the Andes provides good continuity for organisms found in high-Andean steppe vegetation. However, from here southward, under present-day climates, southern Andean steppe occurs on a myriad of isolated, island-like summits, as occurs in páramo. As in the northern Andes, the Pliocene and Pleistocene glacial cycles were associated with significant fluctuations in the altitude of permanent snow and ice (Thomson *et al.*, 2010). The North and South Patagonian Icefields constitute immense north–south biogeographical barriers in the western Patagonian Andes, whose impact on present-day distributions of high altitude plant species has not been fully studied.

Overall, the evidence indicates that high-elevation habitats are geologically young and their floras are recent. With regards

to the second point, the most recently evolved species of *Polylepis* (Rosaceae) are distributed at the highest elevations (Simpson, 1979), and this also appears to be true for some species of *Centropogon* (Stein, 1992) and *Fuchsia* (Godley and Berry, 1995). In relation to geological age, the Northern Andes had reached no more than 40% of their modern heights between 15 and 5 Ma, but as of 2–5 Ma rose rapidly to reach their modern elevations by ~2.7 Ma (Gregory-Wodzicki, 2000). By the Late Pliocene/Early Pleistocene (1–2 Ma), a floristically impoverished version of páramo came to occupy large areas between 2000 and 3000 m (Sklenář *et al.*, 2011). The Altiplano had attained no more than a third of its present elevation by 20 Ma, and no more than half its modern elevation by 10 Ma (Gregory-Wodzicki, 2000). Based on the paleoaltitude projections given by Hartley (2003) the Western Cordillera would have reached about 3500 m by about 8 Ma, whereas the Eastern Cordillera and the Altiplano did not reach an equivalent height until <5 Ma and perhaps as late as 3 Ma.

Less is known about paleoaltitudes in the southern Andes. According to Quinteros *et al.* (2005) the Patagonian Andes attained some 400 m elevation by the early-middle Miocene. Blisniuk *et al.* (2005) suggest that uplift of the Patagonian Andes was already sufficient to produce a west–east rainshadow by 16.5 Ma. From Thomson *et al.*'s (2010) recent work, the Andes at 38–40° S seem to have reached around 1800 m in places by 10 Ma. Here the modern treeline lies at around 1400–1500 m, but it must be remembered that the climate today is cooler than at 10 Ma. In any case, because far less uplift is required to support high-elevation vegetation at the southern extreme of the continent, southern Andean steppe probably appeared earliest (cf. Simpson, 1983; van der Hammen and Cleef, 1986), followed by the puna, and finally the páramo where the treeline develops at much higher altitudes. In accordance with the hypothesis of an older southern Andean steppe, Simpson *et al.* (2009) showed that páramo and puna species of *Perezia* diverged later than their southern Andean counterparts. Hershkovitz *et al.* (2006a) showed that the very large high elevation predominantly puna clade comprising *Chaetanthera* subgenus *Egania* diverged at about 3.5 Ma in comparison with a smaller southern Andean steppe clade in subgenus *Oriastrum*, which dates to about 11 Ma. The genus *Oreobolus* (Cyperaceae) is believed to have colonized into the southern Andes at around 5–5.6 Ma from Australasia, to eventually make its way into the northern Andes (Chacón *et al.*, 2006).

Plant Biodiversity in High Elevation Andean Habitats

Here the current state of knowledge concerning plant biodiversity in the entire South American high-elevation belt is reviewed.

Species Richness

Most floristic work in the high Andes pertains to surveys of local areas (e.g., Méndez *et al.*, 2006), altitudinal transects (e.g., Arroyo *et al.*, 1988), or to a particular vegetation zone (e.g., Luteyn, 1999). Where plot data exist, it has been taken using a variety of plot sizes. The high level of physical continuity along

the Andes reflected in the distribution of many plant genera in more than one, and often across the three vegetation zones, makes it imperative to take a broad view of the high-elevation habitat. The first question that may be asked concerns how many plant species inhabit the entire Andean corridor. Arroyo *et al.* (2010) provided a preliminary estimate of 6700 vascular plant species in 870 genera, indicating a very rich high-elevation flora. This number incorporated all páramo species found in the Andes as per Luteyn's (1999) páramo list. Such high species richness in the high-elevation belt is not surprising given the north–south trending nature of the mountain range associated with a great variety of climates and the high-topological diversity already alluded to. These last factors, in addition to providing an outstanding number of environmental niches in the high-elevation belt itself, are associated with a high diversity of subtending lowland vegetation types (cf. Arroyo *et al.*, 1983 for the range of vegetation types in the Chilean Andes), ranging from closed tropical and temperate forests through Mediterranean-type scrublands to open steppe grasslands and desert communities, all providing an outstandingly rich source of evolutionary lineages from which the high-elevation flora has been partially recruited. Sizable genera in the high-elevation belt include: *Adesmia*, *Astragalus*, *Baccharis*, *Calamagrostis*, *Calceolaria*, *Carex*, *Diplostephium*, *Draba*, *Elaphoglossum*, *Espeletia*, *Festuca*, *Gentianella*, *Lupinus*, *Geranium*, *Gynoxys*, *Halenia*, *Hypericum*, *Huperzia*, *Lupinus*, *Miconia*, *Nototriche*, *Oxalis*, *Pentacalia*, *Poa*, *Puya*, *Senecio*, *Solanum*, *Valeriana*, and *Viola*. *Senecio* stands out above all other genera with an estimated 300 species occurring in Andean high elevation habitats. *Senecio* is followed distantly by *Calceolaria*,

Gentianella, *Lupinus*, *Nototriche*, *Solanum*, and *Valeriana*. By far the largest high elevation plant families globally for the Andes as well as in each of the three high-elevation zones are the Asteraceae and Poaceae.

Our early effort to estimate the size of the high-elevation flora brought forward the many typical difficulties associated with developing a continental-wide checklist for high Andean habitats – poor habitat information on many plant specimens, information not available in a readily accessible form, numerous synonymy problems. In what is an ongoing refinement process some species have been eliminated as better habitat knowledge has come to hand, while others are being added. Additional páramo records are also possible. In his comprehensive treatment of the Columbian páramos Rangel (2000b) points out that many species are missing from Luteyn's (1999) páramo list. Taking these various factors into consideration, the above estimates can be expected to change in the near future.

Information on other plant groups thus far is only available for páramo, which houses 465 species of lichens, 544 species of mosses, and 291 species of hepatics (Luteyn, 1999). Numbers for these groups can be expected to grow substantially as information for the puna and southern Andean steppe becomes available.

Endemism

Andean high-elevation habitats, not surprisingly given their youthful age, support no endemic plant families. However, at the generic level, 64 genera in 22 families (Table 1) for all

Table 1 Sixty-four plant genera considered to be confined (endemic) to the high-elevation vegetation belt in the South American Andes

Apiaceae: <i>Cotopaxia</i> (PA), <i>Laretia</i> (SAS), <i>Perissicoelum</i> (PA), <i>Pozoa</i> (SAS)
Asteraceae: <i>Asciidiogyne</i> (PA), <i>Blakiella</i> * (PA), <i>Calopappus</i> * (SAS), <i>Espletia</i> (PA), <i>Floscaldasia</i> (PA), <i>Gamochaetopsis</i> * (SAS), <i>Huarpea</i> * (PU), <i>Jalcophila</i> (PA-PU), <i>Loricaria</i> (PA-PU), <i>Marticoenia</i> * (SAS), <i>Misbrookea</i> (PU)*, <i>Mniodes</i> (PA-PU), <i>Novenia</i> * (PA-PU), <i>Oriastrum</i> (PU-SAS), <i>Raouliopsis</i> (PA), <i>Werneria</i> (PA-PU-SAS), <i>Xenophyllum</i> (PA-PU)
Brassicaceae: <i>Aschersoniodoxa</i> (PU), <i>Brayopsis</i> (PA-PU), <i>Catadysia</i> * (PU), <i>Dactylocardamum</i> * (PU), <i>Englerocharis</i> (PU), <i>Eudema</i> (PA-PU-SAS), <i>Paradiodoxa</i> * (PU), <i>Petroravenia</i> * (PU), <i>Weberbaueria</i> (PA-PU-SAS)
Cactaceae: <i>Oroya</i> (PU), <i>Yavia</i> * (PU)
Campanulaceae: <i>Lysipomia</i> (PA-PU)
Caryophyllaceae: <i>Pycnophyllopsis</i> (PU-SAS), <i>Pycnophyllum</i> (PU-SAS), <i>Reicheella</i> * (PU)
Cyperaceae: <i>Phylloscirpus</i> (PA-PU-SAS), <i>Zameioscirpus</i> (PU-SAS)
Ericaceae: <i>Plutarchia</i> (PA)
Juncaceae: <i>Distichia</i> (PA-PU), <i>Oxychlöe</i> (PU-SAS), <i>Patosia</i> * (PU-SAS)
Lamiaceae: <i>Kurzamra</i> * (PU-SAS)
Malvaceae: <i>Nototriche</i> (PA-PU-SAS)
Melastomataceae: <i>Bucquetia</i> (PA), <i>Castratella</i> (PA)
Orchidaceae: <i>Myrosmodes</i> (PA-PU)
Plantaginaceae: <i>Bougeria</i> * (PU), <i>Melosperma</i> (SAS)
Poaceae: <i>Anthocloa</i> * (PU), <i>Dielsiochloa</i> * (PU)
Portulacaceae: <i>Lenzia</i> * (PU-SAS)
Pteridaceae: <i>Nephopteris</i> * (PA)
Ranunculaceae: <i>Barneoudia</i> (PU-SAS), <i>Callianthemoides</i> * (SAS), <i>Laccopetalum</i> * (PA-PU), <i>Oreithales</i> * (PA-PU)
Saxifragaceae: <i>Saxifragella</i> * (SAS)
Scrophulariaceae: <i>Aragoa</i> (PA)
Solanaceae: <i>Combrera</i> (SAS)
Valerianaceae ^a : <i>Aretiastrum</i> (PA-PU-SAS), <i>Belonanthus</i> (PA-PU-SAS), <i>Phyllactis</i> (PA-PU), <i>Stangea</i> (PU)

^aThese genera are considered by some authors as part of *Valeriana*.

PA, found in páramo sector; PU, found in puna sector; SAS, found in southern Andean steppe sector. *, Monotypic genus. Information for Páramo mainly follows Sklenář, *et al.* (2011), but eliminating those genera that are only or partially distributed in the Central American páramos; information for puna and southern Andean steppe from Arroyo (unpublished).

intents and purposes are restricted to the high-elevation habitat considered as a single unit (Arroyo *et al.*, unpublished data). In addition to this large number of endemic genera, several other plant genera in the Andes come close to being endemic, as, for example: *Chrysactium*, *Laestadia*, *Ocroya*, *Parastrephia* (Asteraceae), *Lithodroma* (Brassicaceae), *Nastanthus* (Calyceraceae), *Acaulimalva* (Malvaceae), *Hamadryas* (Ranunculaceae), *Lampaya* (Verbenaceae).

Twenty-eight of the endemic genera listed in **Table 1** spill out beyond the limits of the three traditionally recognized vegetation zones. Indeed seven of the endemic genera span all three vegetation zones (**Table 1**). Of the 36 genera that are strictly endemic to one of the three Andean sectors (**Table 1**), 12 are from páramo, 15 from puna, and nine from southern Andean steppe. Counter-intuitively the older southern Andean steppe has the least number of sectorially endemic genera. Overall by far the largest concentration of endemic genera in the high-elevation belt is found in puna (43), followed by páramo (31) and southern Andean steppe (25). Puna not only houses the largest total number of endemic genera but is also the center of diversity for many of the largest endemic genera (e.g., *Nototriche*, *Pycnophyllum*, *Werneria*, *Weberbaueria*, *Xenophyllum*).

Presently it is unknown what percentage of plant species are strictly endemic to the entire Andean high-elevation belt. To ascertain that a species is endemic to a particular ecosystem, it must be shown that it does not occur in any other vegetation type and/or geographical area. Such detailed habitat knowledge is still very fragmentary for many high-elevation species. Luteyn (1992) originally suggested that perhaps as many as 60% of páramo species are endemic to that ecosystem, but later (Luteyn, 1999) came to the conclusion that a realistic approximation of species endemism is not yet possible, for the very reasons expressed above. Briceño and Morillo (2006) concluded that 25% of Venezuelan páramo species are true páramo endemics. There has been no attempt to determine the number of truly endemic puna and southern Andean steppe species at this stage. In any case, if specific endemism were looked at in relation to the entire high Andean corridor, as we have done for generic endemism, it would not be surprising if around 25–30% of all high-elevation species turn out to be endemic. Based on the estimated size of the entire high-elevation flora given above, this signifies that around 1700–2000 high-elevation species in the Andes might be endemic.

Origin and Diversification of the High-Elevation Flora

How the high-altitude flora of the South America Andes has been assembled is a fascinating topic for evolutionary biologists and biogeographers. Phylogenetic studies reveal that multiple sources have been involved: the subtending lowland vegetation types, a wider neotropical source, an austral-Antarctic source and a holarctic source. Phylogenetic evidence also confirms that once clades are able to establish in the high-elevation belt, they are likely to undergo north–south migration (cf. Hughes and Eastwood, 2006). Evidence for more than one independent entry into the high-elevation belt has been found in several genera (e.g., *Chaetanthera*, Hershkovitz *et al.*, 2006a, b;

Halenia, von Hagen and Kadereit, 2003), leading in such cases to increased phylogenetic diversity.

Phylogenies containing páramo taxa were recently analyzed by Sklenář *et al.* (2011). These authors found that temperate and tropical sources contributed about equally to the páramo flora, but that temperate genera of true northern hemisphere origin contributed comparatively more species to the páramo than their southern hemisphere counterparts, in spite of the fact that the arrival of northern hemisphere groups would have occurred through chance long-distance dispersal.

The well known *Espeletia* complex (>130 species) was originally hypothesized to have an ancestor in the subtending montane belt (Cuatrecasas, 1986), and although important advances have been made in understanding the relationships of the complex (Rauscher, 2002), better taxon sampling is needed to iron out the fine details of the colonization process. Several high Andean clades involving a northern hemisphere origin such as *Lupinus* (Hughes and Eastwood, 2006), *Astragalus* (Scherson *et al.*, 2008), *Gentianella* (von Hagen and Kadereit, 2001), *Halenia* (von Hagen and Kadereit, 2003), and *Valeriana* (Bell, 2004; Bell and Donoghue, 2005) have experienced huge radiations in the páramo and puna, and among these are found some of the highest divergence rates ever recorded (Scherson *et al.*, 2008). Although Sklenář *et al.* (2011) found that temperate and tropical sources have contributed equally to the páramo flora, a huge proportion of the very large wet tropical lowland lineages subtending the páramo seem not to have been able to successfully colonize the páramo, presumably because they are less adaptable for life at high altitudes than incoming lineages of temperate origin. It is not clear at this point whether the same holds for the puna and southern Andean steppe. Here there are many examples of moderate to large-sized radiations in genera of South American origin as found in *Chaetanthera* (Hershkovitz *et al.*, 2006a), *Perezia* (Simpson *et al.*, 2009), *Junellia* (ÓLeary *et al.*, 2009), and especially the endemic high-elevation *Nototriche* (see **Table 1**), which is nested in the *Tarasa* clade (Tate and Simpson, 2003), with many other large genera still to be studied (e.g., *Adesmia*, *Acaulimalva*, *Nassauvia*, *Leucheria*, *Werneria*, *Xenophyllum*). The more gradual vegetation transition into the high-altitude environment in the puna and over a large part of southern Andean steppe could be expected to facilitate easier establishment and radiation of clades of South American origin into the high-elevation habitat.

Apart from major radiations that commonly cover two and even three of the major vegetation zones, the high-elevation flora has been enriched by small numbers of high altitude species evolving at different places in the phylogenies of groups mainly centered at lower to midelevations (e.g., *Tropaeolum*, Hershkovitz *et al.*, 2006b; *Malesherbia*, Gengler-Nowak, 2003; *Ourisia*, Meudt and Simpson, 2006) or from migration along the Andean corridor from the initial point of establishment, as seen in case of the arrival of *Astragalus* in páramo (Sklenář *et al.*, 2011) and *Ourisia* in páramo and puna (Meudt and Simpson, 2006) where northward migration has been involved. Although good phylogenies do not exist to ascertain the directionality of colonization, an important source of enrichment in the far southern Andes concerns a number of small endemic South America genera today occurring in the Patagonian steppe as well as at high elevations

(e.g., *Benthamiella*, *Gamocarpha*, *Oreopolus*, *Hamadryas*, *Huana*, *Onurus*, *Bolax*). These genera, along with larger-radiating genera in the southern Andes such as *Azorella* and *Nassauvia*, could have comprised very early constituents of the original South American high-elevation flora. *Hamadryas* is a recently diverged clade within the *Ranunculus* complex (Hoot *et al.*, 2008) and knowledge about when it diverged would shed important light on this important question. Other sources of enrichment include dispersal from an austral-Antarctic quarter. For example, as was already mentioned, *Oreobolus* is hypothesized to have arrived by long-distance dispersal in the southern Andes from Australasia at 5.5–6 Ma (Chacón *et al.*, 2006) to later colonize into the northern Andes. *Abrotanella* is hypothesized to have existed on Antarctica in the mid-late Tertiary, to disperse northward into the Andes as well as into Australasia at around 3 Ma (Wagstaff *et al.*, 2006). Overall, chance long-range dispersal has played an important role in bringing distant clades into the Andean high-elevation flora. Long to intermediate range dispersal has probably also played an important role in extending the latitudinal distributions of many resident clades, and might explain the outstanding success of the Asteraceae, a family which is generally well adapted for wind dispersal.

Twenty-five high Andean endemic genera are monotypic (Table 1). This high Andean biodiversity component is an intriguing one. Phylogenetic studies are now revealing that many of these monotypic genera are turning out to be embedded in other larger Andean clades. For example, southern Andean steppe *Laretia*, a dominant cushion plant in the central Chilean Andes, is sister to *Azorella madreporica* distributed in the puna (Nicolas and Plunkett, 2009). Until recently, *Urbania* was recognized as a monotypic genus of the puna, where it occurs at very high elevations. ÓLeary *et al.* (2009) showed that it is embedded within a well supported clade of *Junellia*. Subsequently, it was transferred to *Junellia* (ÓLeary *et al.*, 2011). The high Andean monotypic cushion genus *Patosia* forms a well-supported clade with *Oxychlœa*, another small Juncaceae cushion genus (Table 1) (Záveská Drábková and Vlček, 2009). Monotypic *Oreithales* centered in the puna and páramo is nested within a clade of *Anemone* (Meyer *et al.*, 2010), as is the slightly larger southern Andean steppe endemic high-elevation genus *Barneoudia* (Ranunculaceae). *Laccopetalum* and *Krapfia* (occurring also at lower altitude) are sister to one another, and belong to a terminal branching clade of the core *Ranunculus* group (Hoot *et al.*, 2008); however, taxon sampling in *Krapfia* is presently insufficient to determine whether *Laccopetalum* diverged earlier than *Krapfia*. Overall, phylogenetic results tend to suggest recent origins for many of the high-elevation monotypic endemic genera. However, in other cases, relictual status seems more likely, as seen in the basal position of the endemic monotypic *Caloppapus* (Asteraceae) of the central Chile Andes with respect to a clade of *Nassauvia* and *Triptilion* (Simpson *et al.*, 2009). Likewise, *Huarpea*, which is basal to a clade of *Barnadesia* (Gruenstaedtl *et al.*, 2009) – the latter a genus of montane and lowland forest habitats in the Andes and Brazil – could turn out to be a relic taxon. The rare monotypic austral alpine genus *Saxifragella* was found to be deeply embedded in arctic and northern hemisphere *Saxifraga sensu stricto* and is considered to have arrived in the South American Andes via long-distance dispersal (Soltis *et al.*, 2001), perhaps at an early

stage. A fascinating case concerns *Kurzamra* (Lamiaceae), a monotypic dwarf shrub occurring at the upper limits of the vegetation. In a well sampled phylogeny *Kurzamra* occurs in a fairly well-supported clade with species of *Cuminia*, a small woody endemic genus of the Juan Fernández islands (Bräuchler *et al.*, 2010). This relationship suggests that extinction of intermediates in the intervening Atacama desert might have occurred. Alternatively chance of long-distance dispersal into the high Andes associated with rapid morphological evolution might have been involved. To advance in our understanding the evolution of these fascinating high Andean genera, dated phylogenies, and often better taxon sampling are badly needed.

Páramo

Páramo occurs above treeline in Venezuela, Colombia, Ecuador and northern Peru and in outlying locations in Costa Rica and Panama outside the Andean cordillera and occurs between 3000 and 5000 m. It is characterized by remarkable constancy in mean monthly temperature but large diurnal temperature fluctuation (Sarmiento, 1986; Rundel, 1994). In contrast to temperature constancy, precipitation patterns in the páramo are exceedingly complex in terms of amount and seasonality (for detailed reviews see Sarmiento, 1986; Rundel, 1994) varying from approximately 600 to 4400 mm (Sarmiento, 1986; Rangel, 2000a), and from a bimodal pattern in the Venezuelan and Colombian Andes facing the Caribbean Sea to a unimodal in Los Llanos (eastern slopes). Further south in the Ecuadorian Andes, the more pronounced dry season tends to shift to midyear, and the bimodal pattern is almost lost.

While much ecophysiological work has been carried out in páramo, little is known about the pollination and breeding systems of páramo plants. A recent study by Barrios *et al.* (2010) showed that several woody species at a Venezuela subpáramo location are highly dependent on insect pollination and amply visited by bees and other insect groups. In *Espletia schultzei*, a strongly outcrossing insect-pollinated species in the tropical Venezuelan Andes, breeding system remains fairly constant among populations (Sobrevila, 1989). However, wind pollination appears at higher elevations (Berry and Calvo, 1989), suggesting a possible deficit of biotic pollinators at the highest elevations, but maintenance of an outcrossing breeding system. Arroyo *et al.* (1983) showed that high Andean wind-pollinated plant species found in southern Andean steppe have larger geographical ranges than biotically pollinated species. The acquisition of wind pollination at the very high elevations in the Andes, as seen in *Espletia*, has probably facilitated dispersal within the páramo habitat.

For the relatively small land area it occupies, páramo is the richest and possibly most endemic high mountain ecosystem in the world, with 3399 vascular plant species in 500 genera (Luteyn and Churchill, 2000). The largest plant families are: Asteraceae, Poaceae, Orchidaceae, Scrophulariaceae, Melastomataceae, Gentianaceae, Ericaceae, Bromeliaceae, Rosaceae, and Fabaceae (Luteyn, 1999). The páramos of Venezuela support 1420 species of angiosperms (Briceño and Morillo, 2006), while those of Colombia support 3379 species and subtaxa of spermatophytes (Rangel, 2000b). Local páramo

floras are generally richer than in the puna and southern Andean steppe (Table 2). Páramo is characterized by major species radiations as seen in the *Espeletia* complex (> 130 species), which includes "Frailejones" (Figure 2). These are giant rosettes that can grow to 5 m tall and live > 100 years (Monasterio, 1980). The spiral arrangement of leaves and their dense layer of hairs together with the retained dead leaves, provide both thermal insulation and protection against UV radiation (Meinzer *et al.*, 1994; Rada *et al.*, 1985). While the emblematic *Espeletia* complex is restricted to páramo, many species of páramo are also found in puna. An interesting biodiversity question here for future research concerns whether southward expansion of páramo clades of neotropical origin, has been more difficult than northward expansion of puna clades.

Subpáramo

Páramo is subdivided into three main altitudinal zones: superpáramo, páramo, and subpáramo (Cuatrecasas, 1968; Cleef, 1981; Ramsay and Oxley, 1997; Jorgenson and León-

Figure 2 Páramo in Ecuador, 3600 m dominated by frailejones (*Espeletia* spp.).

Yáñez, 1999; Luteyn, 1999). Nevertheless, for the Venezuelan páramos, Monasterio (1980) recognizes two altitudinal zones, in Spanish called 'pisos altitudinales': a high Andean zone or

'Piso Altiano' (4000–4800 m) and the upper Andean zone or 'Piso Andino Superior' (2800–4000 m). Here the three main altitudinal zones are reviewed mainly based on information given in Luteyn (1999) and some particular communities mentioned by Monasterio (1980) will be highlighted.

The subpáramo constitutes a transition zone between the upper montane forests and true páramo. Found between 3000 and 3500 m it is comprised of grasslands intermixed with isolated thickets of shrubs and dwarf trees. Representative shrubby plants include species of *Aragoa*, *Berberis*, *Bejaria*, *Hypericum*, *Macleania* and *Vaccinium*, *Brachyotum*, *Miconia*, *Gynoxys*, *Diplostegium*, *Hesperomeles*, and the bambusoid grass *Chusquea*. Small trees in the subpáramo thickets include species of *Buddleja*, *Escallonia*, *Gynoxys*, *Hesperomeles*, *Myrsine*, *Oreopanax*, *Schefflera*, and *Weinmannia*. A number of species found principally in montane cloud forests occasionally inhabit the subpáramo, contributing significantly to the overall high diversity of páramo in general.

True Páramo

True páramo, also referred to as grass páramo, extends from approximately 3500 to 4100 m and is dominated primarily by grasses, in particular species of *Calamagrostis* and *Festuca*. Shrubs of *Baccharis*, *Diplostegium*, *Loricaria*, *Pentacalia*, *Hypericum*, *Gaultheria*, *Pernettya*, and *Vaccinium* are common, as well as rosette and cushion plants of the genus *Acaena* and *Plantago*. The *Espeletia* complex is well represented and several species such as *Espeletia barclayana*, *Espeletia brachyaxanthia*, *Espeletia jaramilloi* and *Espeletiopsis corybosa*, *Espeletiopsis guacharaca*, *Espeletiopsis muiska*, and *Espeletiopsis colombiana* are more or less restricted to bunchgrass páramo. Common herbaceous genera include *Acaena*, *Bartsia*, *Bomarea*, *Cerastium*, *Eryngium*, *Gentianella*, *Halenia*, *Jamesonia*, *Lachemilla*, *Lupinus*, *Lycopodium sensu lato*, *Paepalanthus*, *Senecio*, and *Sisyrinchium*.

Superpáramo

Superpáramo usually occurs at above 4000 m. The superpáramo landscape supports a broad array of mosses, lichens, herbaceous vascular plants (such as *Arenaria* spp., *Cerastium floccosum*, *Astragalus geminiflorus*, *Azorella pedunculata*, *Distigma empetrifolium*, *Draba* spp., *Eudema nubigena*, *Geranium multipartitum*, *Hypochaeris sessiliflora*, *Senecio* spp., *Luzula racemosa*, *Nototriche* spp., *Plantago sericea*, *Valeriana alpifolia* and *Viola pygmaea*), and numerous other grasses. Superpáramo includes a rich collection of endemic vascular plants as typified by *Senecio cocuyanus*, *Senecio adglacialis*, *Senecio supremus*, *Senecio pasqui-andinus*, *Senecio cleefii*, and *Senecio guicanensis*. *Senecio santanderensis* is only known from the Páramo de Santurbán and the Páramo de Almorzadero in Colombia (Rangel, 2000b). The floras of dry and humid superpáramo in Ecuador differ in relation to the importance of tropical and temperate elements, with the latter more abundantly represented in the drier páramos (Sklénár and Balslev, 2006).

Northern Andean Alpine Cushion Formations

Cushion-like plants of the genera *Azorella*, *Arenaria*, and *Montia* can be well developed from 4200 to 4800 m in páramo (Monasterio, 1980). At the highest altitudes these formations may be represented by solitary cushions of *Azorella* spp., which can reach heights of up to 40 cm. In less exposed areas the cushions are accompanied by species such as *Gentiana sedifolia* and *Lysipomia sphagnophila* and various bryophytes such as *Tortula andicola* and *Zygodon pichinchensis*.

Northern Andean Dwarf Polylepis Forest

Scattered patches dominated by dwarf trees of *Polylepis* (Rosaceae) are often found in páramos. Arborescent *Polylepis*, comprising 28 species, is endemic to the high tropical and subtropical Andes (Schmidt-Lebuñ et al., 2006). Palynological studies show that the genus has been established in the Andes for at least 2.7 million years, and certain species are considered to grow at altitudes higher than any other arborescent angiosperm in the world (Hoch and Körner, 2005). Species found in the páramo include *P. lanuginosa*, *P. reticulata* and *P. weberbaueri*, *P. quadrijuga*, and *P. sericea* among others. *P. sericea* has been widely studied from an ecophysiological point of view (e.g., Goldstein et al., 1994; Rada et al., 1996, 2009; Colmenares, 2002).

Puna

Puna occurs from northern Peru south through Bolivia to northern Argentina and northern Chile and is found from 3300–3700 to over 5000 m (Cabrera, 1971; Arroyo et al., 1988; Luteyn and Churchill, 2000). Unlike in páramo, a consistent treeline is lacking throughout much of the lower limit of puna (especially on the western side of the Andes), making the definition of its lower limit for floristic and ecological studies difficult. While diurnal temperature fluctuations are wide, the annual temperature range is low. At Parinacota (18° S) located on the western side of the puna at 4400 m, mean temperature is 1°C, freezing temperatures occur during every month of the year, and diurnal temperature fluctuation can be as high as 30 °C (Torres et al., 1978). North of 24–25° S, the Andean mountains are much drier on the western side than on the eastern side (Sarmiento, 1986; Arroyo et al., 1988), and there is a trend for increasing aridity from north to south. The northern part of the central Andes generates a rainshadow by forcing moisture laden air to rise and cool on their eastern slopes. In central Peru and northern Bolivia, the amount of moisture crossing the eastern cordillera is still relatively high and the vegetation still quite moist on the western flanks. However, in northern Chile and southern Peru, as the air masses descend toward the western Pacific slopes, they undergo further drying on account of the cold surface waters of the Humboldt Current, producing significant aridity above 3000 m in the Western cordillera. Precipitation (mostly in summer as snow) at Parinacota (18° S) on the western side is approximately 160 mm with high variability among years (Rundel et al., 2003); to the east at La Paz (16° S, 4100 m) the puna receives 564 mm per year (Sarmiento,

Figure 3 Puna in Bolivia dominated by *Festuca* spp.

1986). South of 24–25° S the western flanks of the Andes experience a radical shift in climate. Here the scarce puna precipitation is derived from the Polar front and falls mostly during the winter months (Arroyo *et al.*, 1988).

Compared with páramo and southern Andean steppe, the puna landscape is vegetationally less diverse (Figure 3) and can be monotonous in the drier areas. Showy flowers are less frequent than in the páramo and southern Andean steppe. While insect pollination occurs, bee pollination is less frequent, and pollination rates are generally lower than in southern Andean steppe (Arroyo and Squeo, 1990). With increasing elevation and aridity wind pollination becomes more important (Arroyo *et al.*, 1983). Three altitudinal vegetation belts are often recognized in puna: (1) the subalpine belt; (2) a low alpine belt, and (3) a high alpine belt where permafrost is usually close to the soil surface and only a few species forming small rosettes and grasses are found (Ruthsatz, 1974; Villagrán *et al.*, 1981, 1983; Arroyo *et al.*, 1988).

Local puna floras, especially in dry and desert puna, are generally more impoverished than in the páramo and in southern Andean steppe (Table 2). Currently there is no published figure for the entire vascular flora of puna. An early estimate of the puna flora of northern Chile came up with 865 species (Arroyo *et al.*, 1997) while for equivalent latitudes on the eastern side of the Andes in Argentina the estimate is for 1034 species (Novara, 2003), with Asteraceae, Poaceae, Fabaceae, and Solanaceae dominating, and with many species shared on the two sides of the Andes. It has been estimated that the total puna flora, taking its full extent in Peru, Bolivia, Chile, and Argentina into account, could come close to 3000 species (Arroyo, unpublished data). Large plant families include: Asteraceae, Poaceae, Fabaceae, Malvaceae, Solanaceae, Caryophyllaceae, Gentianaceae, Brassicaceae, Valerianaceae, and Calceolariaceae. Compared with páramo, it can be seen that there are fewer large families with tropical affinities in puna. The authors caution that the puna is by far the most difficult of the three Andean areas to delimit physically, such that the estimate given here is likely to change in either direction on more detailed study. Despite the very different climates of páramo, puna, and southern Andean steppe, and some significant biogeographical barriers, several genera

centered on the puna have representatives in páramo and/or southern Andean steppe, among them *Werneria*, *Xenophyllum*, *Nototriche*, *Weberbaueria*. Until good phylogenies become available, of course, it cannot be ascertained whether these genera originated in the puna to migrate north and south.

Humid Puna

Humid puna extends from north central Peru adjacent to the páramos (jalcas) in southeasterly direction to along the eastern margin of the Altiplano and Eastern Cordillera of Bolivia, with a small southward easterly extension into Argentina (Cabrera, 1968). Annual precipitation ranges from 400 to 1500 mm. It supports a well-developed plant cover and is often dominated by an uninterrupted carpet of grasses (e.g., *Calamagrostis*, *Festuca*, and *Stipa*). Other common genera of the humid puna include prostrate, rosette, or cushion species of *Azorella*, *Daucus*, *Baccharis*, *Werneria*, *Draba*, *Echinopsis*, *Gentiana*, *Geranium*, *Hypsela*, *Isoetes*, *Lilaeopsis*, *Lupinus*, *Nototriche*, *Ourisia*, *Oxychloe*, *Oriastrum*, *Plantago*, and *Pycnophyllum*, low shrubs in *Adesmia*, *Calceolaria*, *Mutisia*, *Satureja*, *Tetraglochin*, and several species of *Senecio* of diverse habit. A good number of species puna species are shared with páramo.

Dry Puna

Dry puna is found in southern Peru just north of Arequipa, from along the western Altiplano of Bolivia, in northernmost Chile to around 20° S and comprises practically all of the puna found in northwestern Argentina, including the fairly moist kind of puna found in Cumbres Calchaquies in the Province of Tucuman (Cabrera, 1968). Rainfall ranges from 100 to 400 mm per year and ground cover is usually less than 50%. At the lower elevations, dry puna is dominated by extensive shrublands and thickets of the resinous tola shrubs, such as *Acantholippia*, *Parastrephia*, *Fabiana*, *Chuquiraga*, *Junellia*, and *Chersodoma*, *Nardophyllum*, *Ephedra*, *Acantholippia*. At higher elevations stiff bunchgrasses of *Festuca orthophylla* become common, interspersed with species of *Nototriche*, *Werneria*, *Adesmia*, *Baccharis*, *Ephedra*, *Senecio*, *Pycnophyllum*, and *Tetraglochin*. The hard cushion plant *Azorella compacta* is commonly found abundantly in dry puna.

Desert Puna

Desert puna is located mostly in the southern part of the Central Andes along the western cordillera of Bolivia and adjacent to the Atacama Desert region of northern Chile. It receives <100 mm annual precipitation. The vegetation is sparse (<15% cover) and local species richness tends to reach its lowest for puna (Table 2); in contrast with more typical elevational gradients, species richness peaks at mid-elevation. Species richness (including the desert edge) drops from 333 species at 18° S in dry puna to 59 at 24° S in desert in the Chilean Andes and is much lower than across the Andes in Argentina (Arroyo *et al.*, 1988). Generally the vegetation is composed of xerophytic plants, including cushion-forming cacti, thorny shrubs, and bunchgrasses such as *Festuca*

orthophylla and *Stipa* spp. Prominent genera include *Adesmia*, *Mulinum*, *Anthobryum*, *Baccharis*, *Chersodoma*, *Cortaderia*, *Fabi-ana*, *Lampaya*, *Lophopappus*, *Margyricarpus*, *Oreocereus*, *Parastrephia*, and *Urmenetea*. A strong floristic break has been detected between desert puna and southern Andean steppe on the Chilean side of the Andes, whose strongest manifestation is seen in the lower puna belts. This has been attributed to extreme aridity at very high elevations at latitude 24–25° S (Villagrán *et al.*, 1983).

Central Andean Dwarf *Polylepis* Forest

More than 20 species of *Polylepis* can be found in humid puna, many with restricted distributions (Kessler and Schmidt-Lebuhn, 2006; Schmidt-Lebuhn *et al.*, 2006). However, species such as *P. tarapacana* found in Bolivia, Peru, and Chile and *P. tomentella* found from Colombia to NW Argentina have wider distributions. *Polylepis* dwarf forests in puna are encountered from about 3700 to 4600 m and in some places they can cover entire high-elevation slopes as on Volcán Sajama in Bolivia. In wet puna the trees are often festooned with mosses, vines such as *Bomarea*, *Loasa*, *Mutisia*, and *Passiflora*, mistletoes (*Tristerix* spp.), and many epiphytic flowering plants (Galán de Mera *et al.*, 2003).

Cushion Bogs and Salar Vegetation

Extensive high azonal elevation bogs (bofedales) are found throughout puna becoming progressively smaller, more widely spaced, and floristically impoverished toward the southern puna limit (Arroyo *et al.*, 1988). Bofedales in humid puna tend to intergrade with the zonal vegetation, whereas in dry and desert puna they become more conspicuous on account of their dark green color contrasted against the more zonal puna vegetation. The flora of these bogs tends to be more uniform latitudinally than the surrounding zonal vegetation (Arroyo *et al.*, 1988), and includes cushion species of *Oreobolus*, *Distichia*, and *Oxychloe*, together with species of *Scirpus*, *Juncus*, *Calamagrostis*, *Lachemilla*, *Colobanthus*, *Werneria*, *Aa*, and *Gentiana*. The large latitudinal distributions of bog taxa have been attributed to good dispersal and the availability of similar azonal conditions along the Andean chain independently of macroclimatic differences.

Large saline deposits representing ancient lakes are also common throughout dry and desert puna (Arroyo *et al.*, 1988). Some of the typical cushion bogs species are able to survive on their edges where there is still some water, but such species as *Distichlis humilis*, *Muhlenbergia fastigiata*, *Salicornia pulvinata*, *Lampaya* spp. *Suaeda foliosa*, *Tessaria absinthoides*, and *Triglochin maritima* tend now to be more common (Beck, 1985).

Southern Andean Steppe

Southern Andean steppe occurs south of the puna to the extreme end of the continent. The lower altitudinal limit is found at approximately 3200 m at 28° S and at 500–600 m in the extreme south. In northern areas a treeline is entirely

lacking. From 31° to 34° S on the western side of the Andes, an open treeline of *Kageneckia angustifolia* (Rosaceae) is found. South of 35–37° S closed-canopy forest forming a well-defined treeline appears. Treeline species can be deciduous or evergreen species of *Nothofagus*, evergreen *Austrocedrus chilensis*, *Araucaria araucana*, and *Pilgerodendron wuifera*, depending on precipitation level and degree of continentality. *N. betuloides* may form krummholz on the wetter western maritime mountains in the southern canal zone (Wardle, 1998), while *N. antarctica* does so on drier easterly mountains.

Southern Andean steppe develops over a large range of precipitation conditions. Most precipitation (which falls mainly in the winter as snow) derives from a southwesterly Pacific source, and in parts of Argentina, from an Atlantic source. Because of the strong west to east rainshadow, the western side of the southern Andes generally receives more rainfall than the eastern side, and this source increases southward to diminish again in the far south. The western side of the Andes is still quite arid at 30° S (242 mm at 3700 m; Squeo *et al.*, 1993) and 33° S (445 mm at 2500 m; Santibañez and Uribe, 1990) (Figure 4), but even more so in adjacent areas in Argentina where mean annual precipitation at Puente del Inca (2720 m) is approximately 200 mm (Méndez *et al.*, 2006). Southward at 40° S precipitation reaches 1746 mm above a treeline situated at 1350 m (estimated from Hijmans *et al.*, 2005) and occurs in both summer and winter. Further south (46° S), but on the eastern side of Patagonian Andes, at an altitude of 1310 m (just above treeline), annual precipitation drops to approximately 717 mm. Based on treeline and climatic characteristics, southern Andean steppe should probably be subdivided into a more northerly section to around 35–37° S and a southerly section extending to the end of the continent.

Southern Andean steppe is mostly dominated by a mixture of perennial herbs, low rounded shrubs and cushions plants, with accompanying grasses, the latter rarely as dominant as in puna. Plants of this high-elevation Andean vegetation zone have developed numerous adaptations for survival, including some the highest tolerance levels to freezing temperatures ever reported, these involving different physiological mechanisms (Squeo *et al.*, 1996; Sierra-Almeida *et al.*, 2009, 2010;

Figure 4 *Tropaeolum polyphyllum* in the subandean vegetation belt, southern Andean steppe, 32° S, 2400 m, Valle de Juncal, Chile.

Sierra-Almeida and Cavieres, 2012). Deep rhizomes or tap-roots, and fleshy leaves are commonplace. Growth forms are highly diverse. At the higher elevations, many species form flat cushions or dense mats, which can withstand strong winds and cold air-temperatures. Cushions can be herbaceous (e.g., *Oreopolus glacialis*), semiwoody (*Oxalis erythrorhiza*), or woody (*Adesmia caespitosa*, *A. subterranea*, *Azorella monantha*, *Laretia acaulis*). Low rosettes are common (e.g., *Barneoudia major*, *Pachylaena atriplicifolia*, *Nastanthus spathulatus*). The high-altitude conditions are also associated with interesting reproductive adaptations. Many species, including on the southern extreme of the continent, have large, brightly colored flowers and have been shown to be insect pollinated (Arroyo *et al.*, 1982; Arroyo and Squeo, 1990; Squeo, 1991). In central Chile species found in the lower part of the southern Andean steppe are mainly biotically pollinated by a rich array of bees, butterflies, and flies (Arroyo *et al.*, 1982, 1983, 1987). With increasing altitude, and colder temperatures bee pollination declines in frequency as do flower visitation rates (Arroyo *et al.*, 1985), while fly and butterfly and wind pollination tend to increase in frequency (Arroyo *et al.*, 1982; Arroyo and Squeo, 1990). Despite the very harsh environmental conditions a surprising number of plant species in the Patagonian alpine are genetically self-incompatible and dioecious (Arroyo and Squeo, 1990).

Knowledge of the floristic composition of southern Andean steppe at different latitudes along both sides of the Andes is now fairly good (Table 2). Local richness tends to be higher than in the puna and can approach that at some páramo sites. In spite of good local knowledge, there is no published figure for total species richness in southern Andean steppe. From the authors' ongoing work, it has been estimated that the southern Andean steppe contains around 1400–1500 species. As in the puna, a lack of a treeline over a significant part of the southern Andean steppe often makes decisions as to where a species belongs to this particular vegetation zone very difficult. The largest plant families are: Asteraceae, Poaceae, Fabaceae, Brassicaceae, Cyperaceae, Apiaceae, Violaceae, Solanaceae, Calceolariaceae, and Boraginaceae. Important and interesting genera are *Acaena*, *Adesmia*, *Anemone*, *Astragalus*, *Azorella*, *Barneoudia*, *Berberis*, *Bolax*, *Calandrinia*, *Calceolaria*, *Caltha*, *Carex*, *Cerastium*, *Chaetanthera*, *Chuquiraga*, *Colobanthus*, *Descampsia*, *Draba*, *Empetrum*, *Ephedra*, *Erigeron*, *Eudema*, *Festuca*, *Hamadryas*, *Haplopappus*, *Jaborosa*, *Juncus*, *Laretia*, *Leucheria*, *Luzula*, *Montiopsis*, *Moschopsis*, *Mulinum*, *Mutisia*, *Nassauvia*, *Nastanthus*, *Olsynium*, *Oreopolus*, *Ourisia*, *Oxalis*, *Oxychlœ*, *Patosia*, *Perezia*, *Pernettya*, *Phacelia*, *Poa*, *Ranunculus*, *Rhodophiala*, *Ribes*, *Saxifragella*, *Saxifragodes*, *Schizanthus*, *Stachys*, *Stipa*, *Tropaeolum*, *Viola*, *Weberbaueria*, among others. Some cushion species support rich associations of species (Cavieres *et al.*, 2002, 2006; Arroyo *et al.*, 2003). This so-called “nurse effect” has been shown to result in a net increase in species richness at the community level (Cavieres and Badano, 2009).

Latitudinal Variation and Altitudinal Zonation

In the more northerly sector of southern Andean steppe on the western side of the Andes three altitudinal subdivisions are usually recognized (Arroyo *et al.*, 1981; Squeo *et al.*, 1993;

Teillier *et al.*, 1994; Cavieres *et al.*, 2000a), each with a characteristic flora and life forms. On the Argentine side of the Andes vegetation belts are less clearly delimited (Chiapella and Ezcurra, 1999; Ferreyra *et al.*, 1998).

At 33° S in central Chile the subandean scrub belt occurs between 2200 and 2600 m and is characterized by the dominance of prostrate shrubs; a lower Andean belt occurs between 2700 and 3100 m and is characterized by the dominance of cushion plants; and an upper Andean belt occurs between 3200 and 3800 m, and is characterized by a sharp decrease in vegetation cover, with dominance of tussock grasses and small rosette plants. Typical shrub species in the subandean belt are *Acaena splendens*, *Anarthrophyllum cummingii*, *Berberis empetrifolia*, *Chuquiraga oppositifolia*, *Mulinum spinosum*, and *Nassauvia axillaris*. Annual species such as *Colomia biflora* and *Chaetanthera* spp., and geophytes, such as *Rhodophiala rhodolirion* and *Zoellneriallum andinum* are not uncommon here. Cushion plants such as *A. monantha* and *Laretia acaulis* are the dominant species in the lower Andean belt, where herbs and subshrubs such as *Nassauvia pyramidalis* and *Senecio francisci* also become important in terms of vegetation cover. Typical elements of the upper Andean belt are small herbs and rosette forming species such as *Nassauvia lagascae*, *Oxalis compacta*, *Chaetanthera lycopodioides*, *C. apiculata*, *C. pusilla*, *Nassauvia pinnigera*, *Viola atropurpurea*, and *V. philippii* and cushions such as *Azorella madreporica* and *Oreopolus glacialis*. Many of these same species and others occur on the Argentinean side of the Andes (Chiapella and Ezcurra, 1999; Ferreyra *et al.*, 1998) where local species richness can be very high (Table 2).

Further south in the wetter Patagonian Andes two main above-treeline vegetation belts are discernable: (1) a low andean belt from treeline to around 800–950 m (Figure 5), dominated by large cushion species such as *A. monantha*, *Abrotanella* spp., *Adesmia salicornia*, and *Bolax gummifera*, accompanied by the low prostrate shrubs *Empetrum rubrum* and *Pernettya pumila* and perennial, sometimes loose mat-forming herbs such as *Adesmia villosa*, *Azorella filamentosa*, *A. fuegiana*, *Calceolaria uniflora*, *Ourisia breviflora*, *Oxalis loricata*, *Perezia pilifera*, *Senecio magellanicus*,

Figure 5 Lower alpine belt in the Patagonian Andes, Cordillera Darwin, Tierra del Fuego, 55° S, approximately 600 m, Chile, dominated by the cushion species *Bolax gummifera* (Apiaceae).

and *Luzula* spp. and (2) a high alpine belt composed of hemi-cryptophytes, subshrubs, and grasses including *Hamadryas kingii*, *Moschopsis rosulata*, *Perezia megalantha*, *Nassauvia lagascae*, *Nassauvia pygmaea*, *Leucheria leontopodioides*, *M. nordenkjoldii*, *Saxifraga magellanica*, *Poa alopecurus*, and occurring to 1200–1400 m (Arroyo *et al.*, 1992). Very rare plants such as *Epilobium conjugens*, *Saxifragodes albowiana*, *Tetrachondra patagonica*, and circumpolar *Azorella selago* may be found in very wet areas. On the drier more continental eastern Patagonian mountains, where a treeline can be lacking, and where the effect of the Pleistocene glaciations is less evident, these same vegetation belts are displaced upward by about 200 m, and are noticeably richer in species than their western counterparts (Arroyo *et al.*, 1989). On these eastern mountains are found many additional species of *Adesmia*, *Draba*, *Leucheria*, *Oxalis*, and especially *Senecio*, as well as several species belonging to genera endemic to Patagonia, among these, *Hamadryas*, *Benthamiella*, *Saxifragella*, and *Onurus* (Arroyo *et al.*, 1989; Iribarren and Ferreyra, 2011). Many different taxa have evolved the cushion habit, for example, *Plantago uniglumis*, *Benthamiella azorella*, *Benthamiella nordenkjoldii*, *Hamadryas sempervivens*, *Oreopolus glacialis*, *Valeriana (Aretiastrum) sedifolia*. Local richness on these easterly Patagonian mountains is surprisingly high (Table 2).

High Andean Bogs and Seeps

On wet sites throughout southern Andean steppe cushion bog communities and seeps often called ‘vegas,’ or ‘mallines’ develop. In the northern part of the southern Andean steppe at high elevations, these are dominated by cushion species, namely of the genus *Oxychloë* and *Patosia clandestina*, which in turn are accompanied by a rich array of perennial herbs and forbs such as *Antennaria chilensis*, *Azorella trifoliata*, *Calandrinia caespitosa*, *C. acaulis*, *C. affinis*, *Cardamine glacialis*, *Caltha appendiculata*, *Colobanthus quitensis*, *Eleocharis albibracteata*, *Luzula* spp., *Nastanthus caespitosus*, *Phylloscirus* spp. In the Patagonian Andes, the bogs tend to be softer and are composed of a mix of perennial herbs, forbs and grasses, such as *Acaena antarctica*, *Acaena magellanica*, *Caltha appendiculata*, *Carex vallis pulchrae*, *Erigeron leptopetalous*, *Eudema hauthalii*, *Hamadryas sempervivoides*, *Juncus scheuzerioides*, *Plantago barbata*, *Primula magellanica*, *Marsippospermum reichei*, and *Trisetum*, *Deschampsia Agrostis*, *Poa*, and *Phleum* spp. On the wetter western Patagonian mountains, hard cushion species more typical of Magellanic moorland (e.g., *Caltha dionaefolia*, *Oreobolus obtusangulus*), can also be found occasionally in alpine bogs.

Concluding Remarks

In what has been a rapid flight along the Andes the authors have attempted to overview the state of knowledge of plant biodiversity in the high-elevation habitat. This has not been an easy task, as most work pertaining to the high Andes has been carried out by researchers from many different countries, with a tendency for them to work independently and often using different concepts to define and divide the high-elevation habitat. Difficult access to high-elevation areas in the Andes has clearly hindered a more systematic approach to

describing biodiversity and much of the available floristic information is not appropriate for more quantitative analyses. Nevertheless, as was seen, significant progress has been made in relation to documenting the composition of local floras, in developing a comprehensive continental-scale plant checklist and sectorial lists, and in our understanding of the evolution and diversification of the high-elevation flora. But clearly, much work remains. Developing a unified scheme to describe altitudinal zonation in the high-elevation belt and determining the real extent of overlap of the páramo, puna, and southern Andean steppe with a bioclimatically defined montane belt are two urgent tasks. Likewise, adopting standardized sampling procedures, such as plot size to compare local species richness along and between altitudinal gradients at different latitudes is necessary. In attempting to develop a comprehensive high Andean plant checklist, the authors have been struck with the poor quality of habitat data on many herbarium specimens, and the rarity of online georeferenced plant specimen databases in the Andean countries, where many herbaria and excellent collections exist. Apart from the need for well-resolved phylogenies for many more plant genera, undoubtedly, one of the most promising areas for future research concerns niche evolution of high-altitude plants in the phylogenetic space. With their outstanding range of climatic conditions, diverse flora, and many morphological, reproductive and ecophysiological adaptations for survival in the harsh high-altitude habitat, the high Andes are well positioned to contribute to fundamental integrative research of this kind. Finally, much of the high-elevation habitat in the Andes is still quite well conserved, but certainly not without threat, for example, by the mining industry.

Acknowledgments

Research support from several Fondecyt-Chile grants, the Chilean Millennium Scientific Initiative (F ICM P 05-02) and the Conicyt Base Financing Program (PFB-23) has enabled much of the Chilean and wider Andean research referred to in this article. Interaction with the GMBA program of DIVERSITAS has been very useful.

Appendix

List of Courses

1. Alpine Ecology
2. Biodiversity
3. Biogeography

Glossary

Acidophilic Organisms preferring or requiring a low pH environment.

Chemoautotrophs Organisms able to synthesize organic compounds by the oxidation of energy-rich inorganic sources. Light is not used.

Cyanobacteria A group of bacteria containing chlorophyll and capable of photosynthesis.

Eucaryotes Organisms possessing a defined cell nucleus and nuclear membrane. Includes all organisms above the level of the procaryotic bacteria.

Frustule The hard, silica-containing skeleton of diatoms (green algae).

Geothermal heating Water heated at depth in the earth and released to the surface as thermal outflows.

Heterotrophs Organisms dependent for their energy on organic compounds. If oxidized, the process is aerobic. When oxygen is absent, the process is anaerobic (fermentation).

Metazoa Organisms whose individuals have more than one cell (multicellular).

Photoautotrophs Organisms able to synthesize organic compounds from water and inorganic nutrients, using the energy in photons of light.

Procaryotes Organisms without a defined cell nucleus or nuclear membrane.

Protozoa A group of eucaryotic organisms usually classified as animals and regarded as primitive. But some

major problems exist with some protozoa such as slime molds and euglenoid forms, which share many of the properties of plants.

Solar heated Water raised to temperatures significantly exceeding the regional temperatures of lakes and streams. Many of the thermally tolerant and thermal-opportunist groups are thought to have evolved in shallow solar-heated ponds and water margins.

Thermal opportunists Organisms that have developed life history characteristics that permit the exploitation of temporary cooler spots in thermal systems.

Thermal systems Outflows of geothermally heated water, usually thought of in terms of those at the surface of the earth (see *thermal vent*) where light is present.

Thermal vent Geothermally heated water issuing from cracks in the ocean floor. Very high temperatures and pressures and the complete absence of light are characteristic.

Thermally tolerant Organisms able to live at temperatures significantly higher than the regional norm. They can also exist at cooler temperatures, but may not compete well in the latter situation.

Thermophily Often restricted to mean those organisms adapted to living at high temperatures and unable to survive at lower temperatures. In this chapter the term is also used in a more general way to characterize any type of adaptation to thermal systems.

Extreme Environments

The diversity of organisms in thermal environments is determined, in common with all biodiversity, by the interactions of the physical/biotic environment with the adaptive abilities of individual species populations. But in some respects thermal environments (ecosystems) are quite different, even unique, compared to ecosystems dominated by weather, geological origins of soils, and patterns of precipitation and drainage. First of all, thermal ecosystems form a class of extreme environments characterized by a mean temperature markedly higher than “normal.” (Other extreme environments possess one more environmental variable far outside the “norm”—for example, arctic, desert, brine lakes, low pH systems, etc.) Some of these, such as the arctic/antarctic frozen wastes and extreme deserts, are caused by widespread climatic factors and are typically very large, whereas thermal ecosystems and some other extreme environments are small and result from local changes in the physical environment.

What is “normal” and what effect does the extreme factor or factors have on biodiversity? Here I define an extreme

environment as “a condition under which some organisms can grow, whereas others cannot.” This is too general for the purpose of this chapter, because each different ecosystem has its adapted flora and fauna. A more narrow definition identifies the extreme as excluding entire higher taxonomic groups, not simply species. Thus the extreme environment is not only low in the diversity of species, but also low in the diversity of higher orders of classification as well.

Thermal Systems—General Characteristics and Definitions

Among extreme environments, thermal ecosystems are defined as those with an elevated temperature, compared with the range of other ecosystems found at the same latitude and elevation. The source of the heat may be (a) solar energy, (b) anthropogenic activities, or (c) geothermal. The organisms inhabiting these heated ecosystems can be classified as thermophilic, thermal tolerant, or thermally opportunistic. The first of these, thermophiles (the general term used in this chapter),

require the high temperature for survival to which they are adapted optimally. Thermally tolerant organisms have evolved mechanisms to enable them to exist at extreme temperatures, but they can also survive at lower temperatures. Indeed, in culture they might do better physiologically at these lower temperatures. Competition with other nonthermal species may, however, restrict their distribution in nature. Thermal opportunists, on the other hand, have evolved mechanisms to avoid the effects of direct immersion in hot water. They seek out and take advantage of temporary refugia by using rapid maturation times, rapid mobility, and short life histories. I will later discuss the evolution of these traits and the groups to which they apply.

Solar heating of vascular plant leaves and of the soil/litter surface is enhanced by dark coloration, abundance of sunlight, and the slope of the land surface. Temperatures of plant leaves in desert environments may reach 60 °C; the same temperature applies to soil/litter systems, but it is commonly much lower, and the soil litter surface cools rapidly at night and during rains. Furthermore, the soil/litter surface (as well as plant leaves) heated by the sun is very thin because of its insulating value, and the system is very dry when heated. Thus motile organisms can move out of these thermal systems during periods of inhospitable temperature regimes. Vascular plants can avoid the effects of heat by being rooted in the cooler subsurface soil, and nonmotile microorganisms resist the thermal effects by forming spores or other heat-resistant quiescent stages. The net result is that there is little effect of solar heating on the biodiversity of these ecosystems compared to adjacent systems with more shading of the soil surface. There may, of course, be a loss of species in the driest of these systems, but as a consequence of lack of water, not of temperature per se. Solar heating may also act on very shallow aquatic systems; the margins of lakes and ponds in temperate and tropical latitudes are examples. This can provide a habitat for certain multicelled animals adapted to warm waters, but it does not exclude animals that simply avoid the shallows during the day and forage there at night. Temperature increases are seldom very great, and biodiversity in these systems is affected very little. A case involving a thermally adapted dragonfly will be discussed later in this chapter.

Anthropogenic activities include steam vents, hot water plumbing and heating systems, and fermentation. Where liquid water condenses around steam vents, certain thermal microorganisms can be found and some of them can also be found in hot water systems. But these are too small and transient to be of interest to the student of thermal biodiversity. Fermentation, however, is a large natural phenomenon, as well as the result of certain human activities, such as composting and piling up tailings from coal mines. As a natural process, the accumulation of fermenting organic matter is seldom large enough or accumulating fast enough for the heat of fermentation to significantly increase the temperature. Plant debris added to the soil litter system during the year is simply decomposed at a relatively constant rate and the heat produced is dissipated to the environment. Humans, however, often pile up organic wastes to a degree that the insulating value of the pile causes a rise in the internal temperature, killing, for example, the seeds of vascular plants in

compost heaps and excluding all but microorganisms from the water draining from coal tailing piles. However, the latter effect is often caused more by the extremely low pH of such systems than from elevated temperatures. Although these environments are of little interest from the standpoint of biodiversity, they are of great interest to the student of microbial taxonomy. For example, an entire genus, *Thermoplasma*, is restricted to coal refuse piles.

Geothermally Heated Systems-Classification and Description

The extreme ecosystems characterized by some form of geothermal heating of water are small, both in absolute size (some are only a few square meters or less in extent) and in relation to the surrounding regional climate and soil-dominated areas. Other extreme environments caused by aridity, extreme salinity, and low temperatures stress organisms by posing problems of getting or retaining water. In contrast, geothermal systems have water, indeed they are defined on the basis of hot water. The problems they pose for organisms attempting to survive and grow involve adaptations for tolerating or avoiding the hot water. Biotic diversity is typically low, both in absolute numbers of species and diversity of higher taxonomic groups. This diversity is also usually low relative to the environments surrounding the thermal systems, unless the latter are situated within a larger extreme environment. The deep-sea thermal vents are an example of the latter.

Most thermal ecosystems of the world are caused by the surface emergence of geothermally heated water. The mechanisms of heating involve the percolation of surface water to some depth, where it is heated and pushed again to the surface. The differences in thermal and nutrient characteristics of the emerging water depend on the substrate rocks it saturates after being heated and the length of time the water travels just under the surface before emerging in heated lakes, pools, streams, and spring seeps. Thermal systems are usefully catalogued into four types. These take the form of (a) heated pools or small lakes, (b) small streams, and (c) outflows from thermal springs. These first three types all exist under one atmosphere of pressure or less and the highest temperature found is 100 °C, the boiling temperature at sea level. A fourth type (d) the thermal vent communities form when heated water is ejected at depth on the ocean floor, and temperatures in the hundreds of degrees centigrade are possible. These were first discovered in 1977; they are small, usually less than a few hundred square meters, and may vent water (black smokers) that reaches 450 °C.

The remainder of this chapter focuses on the various manifestations of these heated ecosystems. All of them share the characteristic of being aquatic, but they show differences related to the volume and movement of water flowing out of the ground as well as the mechanisms available to organisms for adapting to the thermal environment. If temperature is regarded as analogous to a toxin, an organism can exist by (a) adapting to exclude the factor (in the case of temperature, this amounts to avoiding lethal levels for a particular stage in the life history), (b) adapting its structure/life history/physiology

to nullify the effects of the factor, or (c) simply adapt in more minor ways to live with the factor. The second and third strategies differ quantitatively but not qualitatively. For example, enzymes can be changed to different temperature optima by relatively small evolutionary steps, but to cope with temperatures that will destroy (denature) the enzyme, a major new structure must be developed.

Geothermally heated lakes and pools characteristically are well mixed thermally, with little or no directional current. This produces, typically, a body of water with a relatively homogeneous temperature regime. The consequences for organisms attempting to colonize such ecosystems is that they cannot escape the thermal load, thus any organisms with limited motility must adapt to survival at the temperature regime of the system. Algal/bacterial mats in such thermal ecosystems, at temperatures where photosynthesis is possible (discussed later), form on the bottom of the lake or pool. There is little or no thermal gradient in these systems, so any eucaryotic consumers must adapt to the prevailing temperature regime or fail to colonize. Thus in Yellowstone National Park in the United States and in other geothermally active areas of the world, the thermal lakes and pools can be ranked from low to higher diversity as an inverse function of the mean maximum annual temperature of the system. Because of the lack of strong currents and replacement of surface water, cooling of these systems is relatively slow and the annual variation in temperature is low, even in the cold temperate latitude and high elevation of Yellowstone Park.

Thermal streams share with thermal lakes and pools the characteristic that the layer of productive organic photo- or chemoautotrophs is on the bottom and organisms attempting to colonize must adapt to tolerate the temperature regime. But the stream has a significant unidirectional flow and hot water emerging from the substrate onto the surface immediately begins to cool. The result is the establishment of a strong thermal gradient from the source downstream, within which different specific conditions for community development can be found. In theory, the cooling curve will be exponential, but other factors intervene, among which the most important are the current turbulence and the temperature, humidity, and the wind speed immediately above the surface of the stream. For example, in a small Yellowstone thermal stream (Gentian Stream, Firehole Lake Drive), I have found that the temperature in summer can fluctuate rapidly as the sun goes behind clouds and wind velocity changes. This effect takes place in minutes, whereas longer lasting weather changes (cloudy days, for example) cause changes in hours to days. In Yellowstone, 250 m from the source, the annual fluctuation in temperature is approximately 20 °C, significant, but also a testimony to the thermal capacity of water since the flow of this small stream is measured in liters per minute. Thus in contrast to the organisms in thermal lakes and pools, the inhabitants of geothermally heated streams are far from living in a constant temperature natural chemostat, unless the stream habitat is very close to the source.

Outflows from thermal springs differ from lakes, pools, and streams in the volume of water discharged, its depth and pattern of flow after discharge, and in the types of communities and organisms that colonize the outflows. In contrast to lakes and pools, spring discharges have strong flows and

turbulent mixing, with a relatively steep thermal gradient established from the source to the point where temperature of the water approximates that of ambient air. Outflows do not generally follow a well-defined channel (except near some of the sources), and in any case the depth is shallow. Once the temperature reaches the point that is tolerated by the filamentous cyanobacteria (blue green algae), a mat of microorganisms forms that can thicken and directly affect the flow of the water. This creates a community with distinct cool patches; some are cool on top with hot water flowing underneath, others are devoid of flow. This temperature heterogeneity provides an additional manner in which motile organisms can colonize thermal communities, by avoiding lethal temperatures as a consequence of adapting physiology, life history, or behavior to take advantage of the temporary cooling of the algal mat. Spring outflows exhibit considerable variety. The sources are of different temperatures, primarily a consequence of the water traveling for variable distances in the soil after emergence from the underlying rock and before emergence onto the surface. The chemical characteristics of the emerging waters may differ (although I am eliminating from this discussion those waters with abnormally low pH, caused by excessive sulfur content). Finally, spring outflows are often intermittent, creating yet another form of temperature heterogeneity. These intermittent flow communities vary greatly in their biotic composition, depending not only on the temperature gradient but also on the period and volume of flow, the chemical composition of the source water, and so on. The biodiversity found at temperatures less than 40 °C is, however, low compared to the biodiversity of similar temperature zones in a relatively constant thermal gradient.

Thermal vent communities are formed by the emission of superheated water from fissures in the ocean floor that form along the line marking the meeting of tectonic plates. Because of the pressure of deep water, temperatures are possible that greatly exceed the 100 °C temperatures of water boiling at sea level. Unfortunately, the great depths at which these vent communities form makes their study both difficult and extremely expensive. In general outline, the water is colonized by strains of high temperature heterotrophic bacteria utilizing the organic compounds dissolved in the superheated water. A strong thermal gradient is set up where the heated water meets the cold seawater and several groups of filter-feeding marine invertebrates have evolved to utilize these resources. Whether this evolution involves tolerance to high temperatures, however, is problematic, since samples and temperatures are hard to match up under such difficult sampling conditions. Furthermore, the thermal gradient is so steep that small distances may see a radical change in mean temperature. Numbers of individuals and biomass of the invertebrate consumers are large, because of the richness of the production by heterotrophic microorganisms, but number of species is low, although perhaps similar or even higher than that of the cold, dark, relatively sterile community away from the thermal vents at these depths. Although the microorganisms are clearly living at temperatures far higher than any found at the surface of the earth, the question of whether multicelled eucaryotes have evolved to survive at temperatures above 40 to 50 °C is still an open question.

Temperature Limits to Life

Extreme environments were characterized earlier by the absence of species belonging to large systematic groups. In thermal ecosystems, as noted earlier, not only are these large systematic groups not found, but within groups, species numbers are low, compared with cool water communities. In general, in terms of temperature tolerance, there is a progression from more "primitive" to higher taxonomic groups, and from small to large individual size. Later I consider the arguments for the evolution of the various temperature tolerance ranges. What are the observed limits, based on sampling and observation of thermal ecosystems?

Four different groups of organisms need to be considered: (a) the heterotrophic procaryotic bacteria, (b) the procaryotic photoautotrophs, (c) the eucaryotic microorganisms, both heterotrophic and photoautotrophic, and (d) the eucaryotic metazoans. Much of the literature prior to 1978 on these limits has been summarized. The study of photosynthetically active thermally tolerant organisms really began with the pioneering work of W. A. Setchell. The main body of his work was never published, but it exists as a 215-page manuscript in the archives of the University of California at Berkeley. A brief summary of the temperature limits portion of this work was published in *Science*. Setchell reported the upper temperature for "algae" as 75 to 77 °C, and for bacteria to be 89 °C. A later investigator claimed, on the basis of superficial samples in Yellowstone, that organisms could not grow above 73 °C, but this work relied on the uptake of radioactive phosphorous as the indicator of life; what was very likely being measured was the upper temperature for photosynthesis rather than the upper temperature for life. In other older records of maximum temperatures, unfortunately, some observers confused blue-green algae, procaryotic cyanobacteria, with green algae, eucaryotes. Within the procaryotes, there has also been confusion about cyanobacteria versus filamentous bacteria. Furthermore, it was not realized how steep the thermal gradient could be, thus putting a premium on temperature measurements at precisely the point where organisms are growing in the field. More recently, the discovery of ocean thermal vents (discussed earlier) has reopened some of the controversy regarding these limits.

Heterotrophic procaryotes have colonized habitats at all temperatures up to the boiling point of water (100 °C) at sea level. The most thermophilic of these organisms have not been cultured, but they are easily sampled in the parent thermal communities using glass slides and simple photomicroscopy. On the basis of these findings, the prediction is that life is possible at any temperature at which there is liquid water. This prediction has now been verified by the preliminary explorations of the thermal vent communities on the ocean floor (discussed earlier) with microorganisms living at temperatures far in excess of 100 °C. However, reports of organisms living in water to 300 °C are still provoking argument. As noted earlier, the most extremely thermophilic procaryotes have not even been cultured. This may be in part due to insufficient knowledge about the nutritional requirements of these heterotrophs, but it might also be due to the difficulty of maintaining cultures near the boiling point of water. The problem is exacerbated in the case of thermal vent

microorganisms growing at both extreme temperatures and pressures. Many of these species are also obligate anaerobes, for which even extremely low concentrations of oxygen are poisonous. Others are endosymbionts, which are also notoriously difficult to culture. Just getting the samples to the surface in a viable condition is a problem, and special culture techniques are required for the methanogens. In summary, thermophilic heterotrophic procaryotes are apparently not limited by temperature but by the presence of liquid water. At the surface this is approximately 100 °C (depending on altitude), but at depth in the ocean life is found at substantially higher temperatures, limited by suitable nutrients, pH, and energy sources.

The temperature limit for procaryotic photosynthetic autotrophs (both cyanobacteria and photosynthetic bacteria) is substantially below 100 °C on the surface. All of the observations and experimental evidence to date suggests a maximum limit of 73 to 74 °C. Of this group the most thermophilic are the photosynthetic procaryotes, of which the most temperature tolerant is the single-celled species of cyanobacterium (*Synechococcus lividus*) and the filamentous photosynthetic bacterium (*Chloroflexus aurantiacus*). These species are found in nature at temperatures up to 74 °C, although the optimum temperature is 63 to 67 °C for the cyanobacteria and even lower, about 55 °C, for the filamentous bacterium. In general, the filamentous forms of the photosynthetic procaryotes seem to have adapted to much lower optimal temperatures than the single-celled forms such as *Synechococcus* sp.

Eucaryotic microorganisms are found in nature at substantially lower temperatures than are procaryotes. Different reactions and responses to thermal environments are found in (a) fungi, (b) eucaryotic algae, (c) protozoa, and (d) metazoans, including invertebrates, vascular plants, and, vertebrates.

Fungi: In general, thermophilic and thermotolerant fungi are found at temperatures lower than 60 °C and occur at this temperature only in acid thermal waters. In the very common and widespread "alkaline" hot spring communities, where the pH is initially somewhat acid because of dissolved carbon dioxide but rapidly rises when exposed to the air, free-living filamentous fungi are absent, even at temperatures below 40 °C. There are reports of fungi parasitic on cyanobacteria that would probably be found at somewhat higher temperatures, but these have not been found in the "alkaline" thermal effluents of Yellowstone Park and are, in any case, poorly known (although there is a remarkable thermal range of the disease-causing fungus, *Dactylaria gallopava*).

Single-celled and filamentous green algae as well as diatoms become abundant at temperatures around 40 °C and below. Earlier reports in the literature of diatoms growing at higher temperatures relied only on the recovery of the resistant siliceous frustules, without demonstrating that the cells were alive or growing. The maximum temperatures for which diatoms can be proved to be surviving and growing is 43 to 44 °C. This particular diatom, *Achanthes exigua*, has an optimum temperature of 40 °C. The single-celled and filamentous green algae have very similar temperature limits to those of the diatoms. Below 40 °C in the "alkaline" thermal outflows of Yellowstone, the diversity of algal species rises (discussed in a later section). Although some mats of filamentous green algae

may be found in these communities on top of mats of filamentous bacteria and cyanobacteria, where the underlying water is much hotter than 40 °C, this is because the green algae is growing on top of the mat and is not exposed to the higher temperature water. This underscores the care needed when measuring the temperature of the environment of suspected thermally tolerant or thermophilic microorganisms. Strong gradients can occur in millimeters between where temperatures are measured and where the organisms are found. An interesting and important exception to the restriction of the eucaryotic algae to temperatures in the range of 40 °C is that of the acido-philic single-celled asexual green alga, *Cyanidium caldarium*. This organism has been studied intensively in Yellowstone Park acid hot spring effluents. The upper temperature limit is 55 to 57 °C, and the organism can be found down to 35 °C. The high temperature adaptation of this acidophilic eucaryote has been explained as a simple matter of no other competition, but the story may be more complicated than that (see next section on the evolution of thermophily).

Protozoa have not been given the attention of other eucaryotes in terms of their occurrence in thermal environments. Determining the temperature limits of this group is difficult because of erroneous reports in the older literature reporting the growth and survival of protozoa at high temperatures. Protozoa will grow readily at temperatures up to 45 °C. Other studies have reported somewhat higher temperatures (57 to 58 °C seems to be the maximum), but the majority of protozoa in the natural thermal systems are found at lower temperatures. I have not found living protozoa in the "alkaline" thermal outflows of Yellowstone at temperatures greater than 40 to 43 °C.

Invertebrates are ubiquitous in and around thermal outflows throughout the world. In surface thermal features many are winged and thus widely distributed. The same genera and species are found in widely separated thermal ecosystems. Some species, such as the water mites, have a juvenile stage parasitic on winged adult insects and are also widely distributed. Those invertebrates that are neither winged nor parasitic are more local in the distribution of species. Most invertebrate inhabitants of thermal ecosystems are motile, thus enabling them to choose, within limits, the space and temperature optimal to growth and survival. Those that are not motile, or only minimally so, such as many of the deep-sea thermal vent invertebrates and the eggs and juveniles of many winged insects are subject to mass mortality when major shifts in current and in the thermal gradient occur. To date, no invertebrates have been found surviving and growing at temperatures greater than the 50 °C claimed for the ostracod, *Potamocypris*. The thermal limits of many of the most abundant and important invertebrate inhabitants of thermal ecosystems are in fact often quite low (well below 40 °C). They exist by quickly colonizing temporary cool spots in the algal mats and growing into motile adults before the thermal environment becomes hot again. These are typical examples of thermal opportunists.

Vascular plants, being rooted in place, can colonize thermal waters at their maximum temperature only if the temperature is extremely stable. Thus there has been little study of their maximum tolerances. Species of *juncus* grow in thermal

streams in Yellowstone Park up to about 40 °C and are often so abundant that they block stream flow and cause minor flooding of adjacent soil. Many species of vascular plant grow along the sides of the streams, one of the more conspicuous is the yellow monkey flower (*Mimulus guttata*). It is difficult to say to what degree this plant is thermal tolerant because it does not grow directly in the hot water; its restriction in thermal basins to the sides of streams may simply reflect the availability of water, since the soil (sinter) beside thermal outflows is very dry. The species is found in wet swampy areas throughout Yellowstone Park and shows a wide range in size, being smallest in the hottest and least fertile environments.

Vertebrates, even more than vascular plants, are absent from thermal environments. One fish, the desert pupfish (*Cyprinodon*) is found in nonthermal (solar-heated) streams of Death Valley, California. Here it tolerates temperatures up to 43.5 °C. But geothermal outflows are too hot, too small, too ephemeral, and vary too much in temperature and flow to support populations of even the small vertebrates. Reports of fish living in very hot water suffer from the same problem of most of the early observations of thermal maxima in organisms—namely, the means of temperature measurement were not sufficient to measure small gradients. Often the natural gradient of the water was such that the fish swam quickly from cool water into warm water to feed and then retreated to their cool refuges. For example, in Yellowstone Park, the many nutrients, particularly phosphorous, added to large, cold water rivers such as the Firehole, create exceptionally fertile and productive rivers. But these inflows also raise the temperature to the point that in summer they create a naturally thermally polluted river. In summer the lower Firehole river often increases in temperature far above the optimum for trout. For example, above the geyser basins in the summer of 1952, the average temperature was 10.2 °C, whereas below the geyser outflows the temperature was 18.7 °C, despite the influx of cold water from nonthermal springs and streams. In September of 1962 the difference was even more marked, 10.6 °C above and 20.0 °C below. That fish are able to not only survive but prosper in this situation is due to the many cold spring and streamside inflows entering the river, where the trout spend the majority of their time, venturing into the warmer currents of the river only to feed for short periods.

The Evolution of Thermophily

Thermophily in general must be thought of as the adaptation of organisms to survive and grow at temperatures (water as used in this chapter) significantly higher than the range of temperature in nonheated waters of the geographic region or climate. I have defined the range of thermal heating and the different types of ecosystem developing from the heated outflows. The types of organisms and their maximal and, where available, their optimum temperatures were discussed earlier. In general, the number of species and the diversity of the higher taxonomic classifications is lowest at the highest temperatures and increases with temperature decrease. The absolute upper temperature for life seems to be set only by the temperature at which liquid water is present. But if heterotrophic procaryotes can evolve to live and grow at these

highest temperatures, why do not the other microorganisms and the metazoans also evolve to exploit higher temperatures? In one of the first (and the most detailed) discussions of the evolution of thermophily, the early arguments about this issue are reviewed and new hypotheses presented. Prior to the mid-1970s, the question of thermophily was regarded primarily as a physiological question, not an ecological one. This despite a wealth of evidence from other types of extreme environments that showed that adaptation to the extreme characteristic did not only have to be physiological, but that competition with other organisms was an important factor.

Several earlier authors regarded the increasing temperature tolerance of metazoa to eucaryotic algae to cyanobacteria (plus fungi) to heterotrophic bacteria as being due primarily to the increasing complexity of the cellular structure. In the fungal eucaryotes and for the eucaryotic green alga, *Cyanidium*, both of which reach 60 °C as the upper maximum, the situation is complicated by the fact that they grow only in low pH hot systems. For the most part the arguments are simple statements that the cell structure has some fundamental property that cannot be overcome by further adaptation. This postulates not only that the fundamental limit exists, but that there are positive selective pressures for the further adaptation to high temperatures. To date there is little evidence for the idea that temperature tolerance is a simple function of cell complexity, nor has the locus of the effect been identified. At first it was thought that the deep sea invertebrates were extraordinarily tolerant of high temperature, and this might have stimulated research into the cellular question. However, recent evidence points to rather low temperature tolerances in these groups. Clearly, no animals have been found living in the "black smokers" where temperatures of 400 °C or more are common. White smokers at about 50 °C may have some fauna, but the majority of the vent fauna is distributed around the vents, in much cooler water at 40 °C or less. Since these temperatures are far above the ambient temperatures of the deep sea, the fauna is, in the sense denned earlier, thermophilic, but will do little to settle the question of why eucaryotes have not evolved to tolerate temperatures endured by thermophilic procaryotes. The essential test of the cell complexity-membrane postulate was to separate the question into: (a) the evolutionary advantage to be achieved above a maximum limit of 62 °C and (b) the evidence that the various eucaryotic genomes have the capacity to respond to the selective pressures if they exist.

Following the preceding argument, the reasoning is that adaptation of eucaryotes to high temperatures could be prevented by some inherent physicochemical limitation or by the lack of benefit in additional resources gained. Two tactics are possible: (a) to shift the range of temperature tolerance at the upper level (the maximum) independently of the lower range and (b) to shift the entire range of temperature tolerance upward. Thermal outflows vary considerably in width, depth, and flow volumes. But the nonlinear cooling process (more rapid at higher temperature differences between water and air/substrate) ensures that the total area of colonization space, and thus of resources (whether solar energy or dissolved nutrients), will become steadily smaller as one proceeds, for example, in 5 °C increments, down the thermal gradient. Thus organisms that can adapt to higher temperatures by

moving only the upper tolerance limit, keeping efficiencies at lower temperatures constant, will always have a positive selective pressure for doing so. If, however, the range must remain the same, shifting it upward will result in an overall loss of resource space. In the latter case, there will never be a positive advantage to be accrued in shifting the range unless other factors are involved, such as predation, competition, or the thermal range of a required food species. Therefore, any general explanation of the evolution of temperature tolerance by themophiles must consider not only a possible physicochemical limitation, but also whether resources are present and the relative amounts of resources at different temperatures. The first of these parameters, physicochemical limits due to cellular differences, has been the focus of most of the early literature. The presence of abundant resources for the various forms of eucaryotic organisms found in and around thermal ecosystems has been well established, to the point where it cannot be invoked as a sole or even a major block to the adaptation to higher temperatures. The invertebrate grazers of the algal mat are restricted to lower temperatures than their food organisms. In the case of photosynthetic eucaryotes, there is the same amount of solar energy per square meter at high temperatures and nutrients are at least as abundant as at low temperatures, if not more so. Thus the question devolves to physicochemical limits or amount of space and therefore of resources. To examine the effect of resource availability (read area) the two tactics discussed above are used. Only populations that are genetically homogeneous or whose genotypes are distributed by random mating fit the criteria. Asexual procaryotes do not fit because changes in genotypic abundance are the result of rates of growth and death. New genotypes arise by mutation and some exchange of genetic material, but the extent of the latter was not known in the 1970s and to my knowledge is not known today in thermophiles.

Because water begins to cool once it emerges from depth into the open air, surface thermal systems typically have the highest temperature water in spring-fed pools with relatively little current and little day-to-day or even annual variation in temperature. At temperatures above the (approximate) 75 °C limit for photosynthetic autotrophs, these pools are dominated by monotypic or very low diversity heterotrophic procaryotes and the pools, although small in absolute area, are virtually infinite in size compared to the size of the bacteria colonizing them. These bacteria are often attached rods or sometimes filaments. Hyperthermophilic bacteria also occur in those thermal outflows where temperatures are 80 °C or above. Because of the current, these forms must be attached rods or filaments. Furthermore, the colonies in the hot outflow channels decrease rapidly downstream. Whether this is because of the decrease in downstream temperature or the development of nutrient shadows is still an open question. Experiments in the field made by enriching these channels with nutrients suggest that the latter may be a more reasonable explanation than the former.

The dominant organism in the high temperature outflows, *Thermus aquaticus*, is an obligate aerobe that forms attached filamentous colonies at temperatures up to 80 °C. Discovered and named in 1969, it now appears to be a complex of several different bacterial types. If the attached bacteria in very hot

outflows do show changes in growth and viability with temperature, it might appear as a broadened range of temperature tolerance. However, this could also be explained as the successive downstream colonization of different genotypes, each adapted to a different optimal temperature. Alternatively, if competition for a scarce nutrient presents a major restriction on distribution, low temperature tolerance will be sacrificed to gain higher temperature tolerance. In this case successive adaptations to higher temperature result in a gain in resources providing the new genotype can maintain a sufficient level of efficiency to gain an advantage over its lower temperature-adapted competitor. Since I have suggested that the apparent temperature response could, in fact, be a response to nutrient depletion, the whole question is still an open one. These colonial forms can be cultured in the laboratory and also can be easily used in field experiments. Some efforts to solve the question of nutrient versus temperature would be worthwhile. In contrast, the extreme thermophilic bacteria that exist in the source pools at temperatures up to the boiling point are very refractory to culture. Thus studying their genetics and measuring their response to temperature clines has been impossible.

In the procaryotic photosynthetic microorganism, the evolution of temperature tolerance was operating in the same way, that is, the adaptation of successive genotypes to higher and higher temperatures, where there is a gain in resources, should be observed. Instead, we observe the complete failure of these organisms to colonize water at temperatures greater than 73 to 75 °C (see discussion on limits presented earlier). The two major resources of the photosynthetic cyanobacteria and the flexibacteria are sunlight and a carbon source (phosphate is abundant in these systems and the organisms fix nitrogen). Cyanobacteria in particular respond positively to increases in free carbon dioxide. Sunlight is intense at the Yellowstone altitude in all shallow-water systems, obviously independent of temperature. Sunlight only becomes limited deep in thick algal mats, thus expanding the thermal range upward by the development of higher-temperature clones will neither increase or decrease the availability of this factor to thin new mats of cyanobacteria. In the "alkaline" thermal flows however, the water typically emerges at a pH in the 6 to 6.5 range due entirely to large concentrations of dissolved carbon dioxide. Therefore, any organism capable of forming genetically homogeneous clones should be able to adapt to higher and higher temperatures by gaining resources (carbon dioxide) at hotter temperatures. Such clones are known for both of the most common genera of cyanobacteria in thermal springs, *Mastigocladus* and *Synechococcus*.

The best evidence for an inherent physicochemical limit on the temperature of photosynthesis would be if the previous conditions were met with respect to resources. But adaptation proved unable to extend the range of temperature tolerance without a significant decrease in the ability or efficiency to use the increased abundance of the resource at higher and higher temperatures. This is exactly the case for *Synechococcus*. When growth (doubling time) is measured as a function of temperature, it is five times longer at 70 °C than at 40 °C. Thus adaptation to higher temperatures results in a rapidly decreasing ability to process a limiting nutrient, even though it (presumably carbon dioxide) is more concentrated at the

higher temperatures. Thus the failure to evolve tolerances above 73 to 75 °C must be due to a temperature dependent reduction in growth rate or a physicochemical failure in the algal cell.

Eucaryotic microorganisms, including single-celled and filamentous forms plus diatoms and free-living fungi, are seldom found at temperatures above the range of 40 to 45 °C, with the exception of some fungi and the acidophilic genus *Cyanidium*. Collections made from six different hot springs in Montana showed a clear and significant separation between the eucaryotic algae and the cyanobacteria; the former were never collected at temperatures greater than 50 °C and the latter showed more species per sample (2 to 5 at 50 to 58 °C, 10 at 35 °C) than the former. But the diversity of the eucaryotic algae was increasing much faster than the cyanobacteria with decreasing temperature. This separation was present in the thermal springs of both Yellowstone and Mount Rainier National Parks. The eucaryotic alga, *Cyanidium*, which exists at much higher temperatures than the other eucaryotic algae, may be subject to quite different selection pressures since it also occupies a variety of adjacent habitats (wet soil) where the temperatures fluctuate greatly, as do the temperatures in the outflows, which are very cool during snowmelt in the spring and the alga disappears, only to reappear in the water when the temperature rises. The argument is made that the evolution of thermophily in this group must take into account these differences plus the fact that hot acid flows have no procaryotic photoautotrophs that could offer competition to *Cyanidium*. The possibility of genetic mixing due to sexual selection in the eucaryotic algae may, together with the increasing area for colonization as the thermal gradient is descended, render the selective optimum temperature lower in eucaryotes than in sets of competing procaryotic clones. This idea needs testing along with the notion of a major physicochemical limit on the eucaryotic cell. The growth of *Cyanidium* at higher temperatures certainly casts some doubt on the latter as a general explanation for the failure of most eucaryotic algae to adapt to temperatures higher than 50 °C.

Metazoans typically have the lowest maximum thermal tolerances of any group of organisms. Here again, the arguments prevailing before the mid-1970s detailing the failure to adapt to higher temperatures invoked some vaguely defined physicochemical limit. In the case of the metazoa, complexity of organization is added to the supposedly inherent limits of the eucaryotic cell. But, as pointed out for other groups, this is only one of the three lines of evidence that must be considered when pondering the origins of thermophily. The other two are the availability of resources, both space and nutrients, and the interactions of resource abundance and evolutionary mechanisms that act to determine fitness. In other words, whatever the physicochemical limit to the evolution of thermal tolerance, simply measuring maximum tolerance rates in the field does not provide evidence, necessarily, that the physicochemical limit has been reached. Clearly, the larger aquatic metazoans could not sustain viable population densities in the small thermal systems, so there would be no selective pressure for them to colonize even moderate to low temperature thermal systems. Thus no fish are found in geothermally heated waters. The few cases of the evolution of tolerance to elevated temperatures in fish involve small

individual size and solar-heated habitats. Here the maximum temperatures tolerated somewhat exceed 43 °C.

The metazoans characteristic of hot springs are the arachnids (water mites), insects (mostly flies), small mollusks (small pulmonate snails), odonates (dragon flies), and, occasionally, ostracods. These groups are neither characteristic of the cold water streams into which the thermal effluents drain, nor of running water systems in general. Rather, they are related to (sometimes the same species as) the invertebrates found in the shallow muddy margins of lakes and ponds, where ambient daily maximum temperatures, due to solar heating, are of the same order as those in which the thermal inhabitants are found. If these low to moderate temperatures are not set by a physicochemical threshold, then the problem is to explain why, in thermal habitats, the species have not evolved more thermal tolerance.

The second factor affecting distribution (mentioned earlier), competition for scarce resources, seems not to be a factor. In every case studied, the grazers on the algae of thermal ecosystems are less tolerant of high temperature than the cyanobacteria on which they feed. Examples are the ostracods in Hunter Hot Springs, Oregon, and the ephydrid flies of the "alkaline" thermal flows in Yellowstone Park. This leaves the interaction of resources and selection determining fitness. Under random sexual mating (with respect to temperature), the direction of the evolution of temperature tolerance will be determined by the relative numbers of surviving offspring from the upper half of the temperature range relative to those from the lower half. But because of the nonlinear cooling curve of water, the size of the upper temperature part of the range will always be smaller than that of the lower half. Thus under a tactic of shifting range, thermophily cannot evolve unless there is nonrandom mating or fecundity or survival is lower at low temperatures. The randomness of mating with respect to temperature differs in the various groups of hot springs invertebrates, depending on life history and behavior. In the flies and dragonflies, mating occurs after emergence and the animals are highly motile, so randomness with respect to temperature of development is assured. The water mites are also highly dispersed as parasitic larvae, but they do spend their adult lives within a relative narrow temperature range and mate there. The smaller mite, *Partruniella*, tends to spend most of its adult life in cooler patches of the cyanobacteria/flexibacteria mat where it feeds on the eggs of the ephydrid flies and, as expected, has a rather low temperature tolerance. The large predaceous mite, *Thermacarus*, lives directly in the hot water and has an upper temperature tolerance 5 to 10 °C higher than the smaller species of mite and just lower than the most temperature tolerant metazoan, the ostracod. This group has no widespread dispersal mechanism, thus nonrandom mating is predicted. They also seem to be limited by food. Not surprisingly, these organisms have evolved the highest tolerance to high temperature of any metazoan.

In summary, current evidence supports the following statements concerning the evolution of thermophily: (a) the heterotrophic procaryotic bacteria seem not to have any physicochemical limit, having evolved to inhabit geothermal systems of any temperature as long as liquid water is present; (b) the photosynthetic cyanobacteria seem to have evolved to the point (73 to 75 °C tolerance) where a physicochemical

limit has been reached; and (c) eucaryotes vary greatly in temperature tolerance, depending on the group, but none has evolved tolerances equal to the maxima exhibited by the procaryotes. In most cases, the observed limits can be explained on the basis of simple selection/fitness processes, without invoking unknown physicochemical mechanisms.

The Biodiversity of Thermal Ecosystems

Species in, using, or around (living from) geothermal ecosystems throughout the world have been the subject of many studies. The earliest intensive work was on the fauna of the hot springs of Iceland. The algae of several hot springs in western India were cataloged in the 1960s. The algae and fauna of warm springs in New Zealand have also been studied, as has the fauna of thermal springs in the Dutch East Indies. The thermal effluents of Yellowstone National Park in the United States have been the subject of both the largest number and most intensive studies of thermophiles of any area in the world. The original studies concentrated on the fauna but also included some observations of the algae (cyanobacteria). Beginning in 1964, detailed studies of the microorganisms living in the hot spring waters of Yellowstone Park were begun. These became both the most extensive survey and intensive experimental protocol yet done on thermal microbiology. At first the focus was on high temperature systems where only one or a few species were found in any given thermal ecosystem. In 1967, I and my colleagues and students began studying the lower temperature thermal ecosystems with higher diversities of microorganisms and a richer food chain involving species of animal acting as scavengers, predators, and parasites. Additional unpublished information has been obtained from 1983 to the present on the thermal ecosystems developing at temperatures below 45 °C. Thus the ecology of the Yellowstone ecosystems can begin to be understood from the standpoints of species diversity and food-chain relationships. In this final section I review what is known about the diversity of these systems, in their various manifestations of temperature and pH, and compare the results with the thermal biodiversity of the deep sea thermal vents, insofar as the latter are currently understood.

High temperature is the most difficult of extreme environmental conditions to which organisms can attempt to adapt. There are many ways to adapt to exist in extreme cold or aridity and resume growth and activity during short seasonal changes in solar warming and precipitation. High salinity can be avoided or salt excreted so extremes can still support a reasonably high diversity. Indeed, many saline ecosystems may appear simple from the standpoint of vascular plant species and the food chains they support, but be relatively high in the diversity of algae and bacteria in the surface sediments. Thus, in every thermal system investigated to date, the biodiversity decreases rapidly with increases in temperature. At their most diverse, thermal system species are measured in the hundreds; their least diverse manifestations are monospecific.

Temperatures near the boiling point of water in Yellowstone thermal systems and elsewhere (85 °C–100 °C) are most common in source pools fed by deep subterranean springs of hot water. These pools vary widely in chemical characteristics,

depending on the mineral content of the rocks through which the superheated water passes on its way to the surface. All such pools have a large volume of heated water with a relatively small inflow/outflow. Currents are small; almost all mixing is by convection or mild bubbling of various gases, often carbon dioxide. Such systems are natural analogues of chemostats, and they are eventually colonized by adapted heterotrophic bacteria (photosynthesis being impossible at these high temperatures). Not surprisingly, competition generally ensures that they are monospecific, or, if chemoautotrophy is possible, the diversity might rise by one or two additional species. Although thermal source pools may be thought small relative to surrounding mountains, forests, and so on, from the viewpoint of microorganisms, these are virtually constant environmental systems capable of supporting immense numbers of individuals. Current ecological theory supports the prediction of dominance by one or a few species in these circumstances. In contrast, the emergence of superheated water from the thermal vents in the deep sea cannot reproduce these constant conditions. Pools of hot water do not exist, but instead a turbulent mixture of water is emitted at temperatures apparently as high as 350 °C or more, directly into cold ocean water near 2 °C. Thus environmental variation in temperature is undoubtedly high and the higher diversity of microorganisms would be predicted. It is impossible, under such variability in temperature, for one species to monopolize the resources of the system. Thus the students of thermal vent microbiology are finding a number of thermophilic species new to science (although no novel genera have been found). The latter may be due to the culture techniques used, which have not been designed for organisms adapted to high pressures as well as high temperatures.

Food chains in the deep sea vent communities are simple and short, because in the absence of light no photoautotrophy is possible. Thus the vents are surrounded by a diverse array of marine invertebrates that ingest the cells and products from the thermal vents. Almost all of these animals are novel species. As many as 236 species of animals have been collected around thermal vents, of which 223 are new to science. This diversity of animal species is far higher than that of any single category of surface thermal ecosystems, although the data represent many different thermal vent locations. If the worldwide diversity of animal species for all known surface thermal features is used, the animal diversity per system is similar in the two types of system. Thus the thermal vent communities of the deep sea, although of great interest from the standpoint of physiological adaptations, mass mortality, and colonization strategy, appear to offer little that is new to ecological theory.

At temperatures below 75 °C and above about 40 °C to 45 °C, thermal outflows form small streams of hot water. These are colonized throughout the world by unicellular photoautotrophic cyanobacteria and filamentous bacteria. These biotic communities are characteristic of all surface thermal features throughout the world, but most early studies were simply endeavoring to determine maximum temperatures. The first rigorous studies of these systems were initiated in Yellowstone Park. In each ecosystem, there are generally two dominant species or species groups at the upper end of this temperature range (a base mat of the filamentous

photosynthetic bacterium, *Chloroflexus*, and an overlying film of the unicellular cyanobacterium, *Synechococcus*). As the temperature decreases, the overlying mat becomes dominated by one or more genera of filamentous cyanobacteria. In relatively constant flows, temperature-adapted strains of *Mastigocladus* are the common dominants; in springs with variable outflows, diversity is often higher due to the presence of additional genera of filamentous cyanobacteria, commonly *Calothrix* or *Phormidium*. When these filamentous forms are able to grow, the outflow begins to go through a definite cycle, because the filamentous mat is not limited to a thin film as are the unicellular forms. As the mat grows, it thickens unevenly; water flows around these thickened areas, producing cool patches. These patches are populated, almost immediately, by one or more species of brine fly (Ephydriidae). Upon hatching, the fly larvae begin to eat and destroy the filamentous integrity of the mat. The pupae metamorphose to adults within a few days. Eventually hot water reenters the cool patch, remaining larvae and pupae are killed, and the cycle starts over in another part of the mat. These flies and their predators are not thermophilic, and in fact are rather thermally intolerant, relative to organisms living in other thermal ecosystems—compost piles, for example. They are an example of what I have termed thermal opportunists, organisms that have adapted their life cycle to take advantage of opportunities provided within the thermal ecosystem. The diversity of the alkaline filamentous mat-fly association is not high for most expressions of this community of 20 to 30 species. Yet a diverse set of food chains and ecological processes is found, photosynthesis, grazing, decomposition, and predation, for example.

When a strongly channeled outflow cools down to 40 °C or below, the diversity goes up rapidly. Metazoan animals can adapt to live directly in the warm water, and eucaryotic algae such as green algae and diatoms invade. Although cyanobacteria are still abundant, they are heavily grazed, and do not form a thick mat. In different expressions of this community are found crustacea, midges (Diptera), and water mites (Hydrachnellae), dominated by a top predator, the larva of the dragonfly, *Erythemis collocatta*. The net effect on diversity is to increase the species numbers to 50 to 60, exclusive of the nonphotosynthetic microorganisms. The latter have not been studied in detail at these temperatures, thus a total diversity of 100 or more would not be unexpected.

Summary

Thermal waters, as extreme ecosystems, exhibit the low diversity expected under such conditions. But high temperature is a particularly difficult factor for adaptive evolution to overcome. Thus, thermal ecosystems appear to have the lowest diversities of any of the extreme environments. Nevertheless, there is considerable variation in diversity, depending on both the temperature of emerging water, the rate of cooling, and the stability of the emerging plume. Generally, there is an increase in diversity as the temperature declines. This can be modified by short-term fluctuations in temperature caused by currents set up in the emerging plume of hot water (in deep sea thermal vents) or by intermittent flows from the source creating cooler periods downstream. Both of these effects increase

diversity. When animals are able to enter the system, a rich ecological food chain (in terms of numbers of ecological processes) often develops.

Acknowledgments

I am indebted for the information in this article to dozens of previous studies of the ecology of thermal organisms. My own work in Yellowstone National Park and elsewhere has benefited from permission from the park administration to do research. I have received financial support from the National Science Foundation through a series of grants, the latest of which, DEB-821-0142, was used to investigate the community forming at temperatures below 40 to 45 °C. I am also indebted to Drs. A. Chalmers and R. Hodson, who provided useful comments on the manuscript. Support for preparation of the manuscript was received as discretionary research funds from the University of Georgia.

Glossary

Assemblage The collection of animals and plants found together in a patch of habitat.

Diversity index A numerical measure combining information about the number of species present in a sample or habitat and information about their relative abundances.

Ecological functions Attributes or properties of assemblages or habitats that are dependent on the biodiversity of animals and plants present. Examples are production of nitrogen, sequestering of heavy metals, sustained production of harvested resources, maintenance of a diverse food-web, and so on.

Ecological processes Direct or indirect interactions between species – such as grazing, predation, competition, responses to disturbance, and so on – that cause spatial or temporal patterns in the distributions and abundances of species.

Patchiness Variation from place to place (or time to time) in the abundances of animals or plants, caused by the interaction of numerous processes.

Recruitment Arrival of new juvenile animals or plants into a habitat or an older stage of the population. For marine animals, recruitment is at some time after the settlement of many planktonic larvae in the adults' habitat.

Intertidal areas such as rocky shores, mangrove forests, sandy beaches, and mudflats are habitats for very diverse assemblages of plants and animals. These species are usually distributed patchily in space and time because of several important ecological interactions. Local biodiversity is therefore patchy and variable. Measurement of biodiversity is complicated by variability. The functions provided by biodiversity are not well understood in most intertidal habitats. Planning for conservation, management, and restoration of biodiversity is difficult because of variability in space and time.

Introduction

Intertidal habitats range from rocky beaches or platforms to sandy and muddy shores. They occur under a wide range of physical stresses, most notably due to emersion when the tide falls and disturbances by waves. The animals and plants must endure the full range of physical variation, from being covered by water when the tide is in, to being potentially exposed to typical terrestrial conditions when the tide is out. In addition, the amplitude or range of tidal rise and fall can vary between two tides in a day (this is called “semidiurnal inequality”) and, everywhere, varies in a fortnightly cycle between spring and neap tides. Spring tides rise much higher and fall much lower than do neap tides. As a consequence, during neap tides, animals and plants at high levels on a shore are not reached by an incoming tide for several days in a row and must endure long periods of inactivity or reduced activity until spring tides start again. At these high levels, moisture from spray (particularly where wave action is great) and during rain is very important for the supply of food and for preventing marine animals from drying out during their long periods of emersion.

In complete contrast, animals and plants at lower levels on the shore are submersed continuously for several days during neap tides because the tides do not fall low enough to expose

such areas to aerial conditions. As a result, the animals and plants are, effectively, in a fully marine habitat and can be subject to predation by crabs, fish, starfish, and so on, which are mostly subtidal species. Such predators can forage at will over the lower parts of a shore during neap tides. This variation in periods of emersion versus submersion causes a very stark gradient of physical conditions from the top to the bottom of the shore.

A second strong physical gradient often exists along a shore, due to variation in wave action. As any shore bends away from being fully exposed to the open ocean, the strength of waves hitting the rocks will vary. As a result, there is a general decrease, with decreasing force of waves, in the amount of splash and spray over any area. The two physical forces – the direct force of waves and the ameliorating effects of splash and spray reducing the influences of desiccation during low tide – influence the abundances of animals and plants and the nature of their activities. Thus, grazing and predation are less intense where waves are strong. The diversity of species changes with wave action because of the combined influences of waves themselves, their ameliorating influence on desiccation, and the indirect influences of both physical features on the interactions among species.

These two major processes – tidal rise and fall and wave action – are so well known that their influences were long considered the major, if not the only, influences on local ecological processes and therefore diversity in intertidal habitats. The general features of intertidal regions, particularly the general patterns of distribution and numbers of species on rocky shores, have for a long time been described in terms of these physical forces. Summaries and details are available in Stephenson and Stephenson (1972) and other reviews of particular biogeographical regions or comparisons of various parts of the world.

More modern syntheses, in contrast, have focused on the ecological processes that have more profound effects in terms of creating and maintaining considerable patchiness in the

ways in which animals and plants are distributed in intertidal habitats. The variation often is considerably more conspicuous than the features considered general and easily explained in terms of gradients of physical forces. This forms the central theme of this contribution – the processes that influence the patterns of distribution and abundance of species and therefore the local diversity of species in intertidal habitats. The major focus is on rocky intertidal habitats because most of the experimental work in the last fifty years has been in that habitat. The animals and plants are typically relatively short-lived (although individuals can live for extraordinarily long periods). They are usually small, abundant, and most of them are slow-moving or sessile. As a result, experimental manipulations to test specific hypotheses from competing models that might explain patterns can be carried out without enormous areas of habitat being disturbed and without excessive costs of logistics and infrastructure. There has been a mass of such work and it has revealed and continues to reveal a great deal about the life histories, interactions, and the general and specific ecology of the maintenance of diversity in intertidal habitats (see the review by Underwood, 2000).

In addition to rocky shores, there is also some discussion of other intertidal habitats (sandy beaches, mangrove forests), even though these are discussed in detail elsewhere in this Encyclopedia. Their inclusion here is to demonstrate that the sorts of variability in time and space found on hard, rocky surfaces are more widespread and general and are not confined to rocky shores.

Following an overview of ecological patchiness and some consideration of its causes in intertidal habitats, three consequences of variability in biodiversity are introduced: how to measure and compare diversity from one place to another, how descriptions of biodiversity may relate to functional aspects of diversity, and the sorts of functions that biodiversity may provide in coastal habitats.

Processes Causing Patchiness on Rocky Shores

Numerous ecological processes influence or maintain patterns of local biodiversity in coastal habitats. These include direct and indirect biological processes of recruitment, predation, grazing, and competition. They also include physical disturbances and biological responses to them. These different types of processes are illustrated here.

Recruitment

Variability in the recruitment of coastal marine organisms is well described (Connell, 1985; Thorson, 1950). Many of the animals and plants have a relatively long dispersive phase in their life history, resulting in a large proportion of propagules being killed by predators, failing to develop, or not being able to find a suitable habitat in which to settle and metamorphose. Inevitably, the processes of production and loss of propagules lead to a huge variation in numbers surviving to settle in the adults' habitat and the number actually settling in any area of habitat at any particular time. This has led to the concept of "supply side" ecology (Roughgarden *et al.*, 1987;

Underwood and Fairweather, 1989; Underwood and Keough, 2001). This is the idea that several ecological processes and their resulting patterns of diversity in assemblages are, at least partially, dependent on the numbers and types of larvae that arrive to grow in any area. For example, predation cannot be an important process in areas where predators fail to colonize as larvae, that is, fail to maintain populations of adults.

There are two major consequences to issues of biodiversity of this variation in recruitment to adult populations. First, vagaries of types and numbers of species arriving on any shore or in any area on a shore will ensure that the diversity of species continues to be patchy at small spatial scales. Second, across the entire ranges over which species disperse, there can be little large-scale variation in diversity. Thus, along a stretch of coastline over which organisms disperse, the assemblages that develop will, in general, receive recruits from similar mixtures of species. When the organisms can keep recruiting via dispersive larvae, populations will persist. Whatever happens in any area, recruitment from other areas will continue. Thus, assemblages will, on average, persist with the same mix of species. In contrast, at the more local scale of patches of coastline, or individual shores, there will be greater variation in the composition of assemblages.

At larger scales, speciation and changes in diversity from one side of an ocean to another are very much influenced by the recruitment of larvae. Thus, the vast stretches of open, oceanic water in the middle of the Pacific and the Atlantic oceans form barriers to the spread or the continuity of species. Scheltema (1971) sampled planktonic stages of the life history of various gastropod mollusks in samples from the middle of the Atlantic. He found a very good correlation between the number of larvae of a given species and the distribution of adults. Species found on coastlines on both sides of the Atlantic were regularly found as larvae in his samples. Larvae that were found less commonly were from adults that had closely related species or subspecies on the two coasts. This implied that the lack of frequent interchange of larvae was causing differentiation and speciation. Species found on only one side of the Atlantic were rare or absent as larvae in the sample. Thus, where larvae cannot arrive, diversity will differ.

The timing of recruitment by different species can also affect the local diversity of species. Thorson (1950) described the predatory brittle stars (*Amphiura* spp.), which do not feed for two months while breeding. Several species of mollusks with short larval development breed during this period. The brittle stars have a longer period of development. As a consequence, the young mollusks could be released into the plankton, complete their development, recruit, and grow to a size where at least some of them would escape from the voracious predatory recruits of the brittle stars. If the mollusks recruited later, they were unable to avoid their predators. This example needs to be examined experimentally, but indicates that the timing and order of recruitment can have profound influences on which species survive in an area.

Initial patterns of recruitment may be less important in determining local patterns of diversity for mobile than for sessile species. Many species of mobile animals can move over the substratum or move up into the water column to drift across relatively large areas in response to local environmental conditions. This not only affects small-scale patterns of

diversity but also contributes to the temporal variation in diversity in any one place.

A final point about the uncoupling of numbers of adults and recruits in any area of coast is that the mixture of different species and the numbers and ages of each species present in some area will not necessarily predict what will occur at any future time. Recruitment of any or all of the species in any diverse assemblage will not necessarily be related to the types or the sizes of populations present there.

Competition and Facilitation

A second major process that can influence local diversity is competition – negative interactions among individuals of the same or different species caused by absolute or relative shortage of resources needed by all of the individuals. In most coastal habitats, resources are food, space, and, for plants, light. Space is needed to settle and become established (for sessile species) and as an indirect resource for food (e.g., by mobile grazers that need relatively open space over which to feed). Alternatively, sufficient space on the substratum is needed to allow access to the water column for filter feeders.

Generally, competitive interactions are considered to lead to a reduction in abundances or actual elimination of competitively inferior species. Numerous examples demonstrate this, starting with Connell's (1961) classic experimental demonstration of destruction of one species of barnacle (*Chthamalus stellatus*) by another, faster-growing species (*Balanus balanoides*, as described in the original papers). As a result of overgrowth by *B. balanoides*, *C. stellatus* could be eliminated from some lower areas of their vertical distribution on a shore.

Such competitive overgrowth can have dramatic effects on the local richness of species. For example, Paine (1974) has described the major decrease in the number of species living on primary space – the underlying substratum – where mussels are able to overgrow and eventually eliminate most other species (limpets, chitons, algae, barnacles).

These examples do, however, paint a biased picture. For example, where mussels overgrow a primary surface, their shells provide new hard substrata on which the inferior competitors can become established. They also serve as “environmental engineers” (Lawton, 1994), because the packed shells of mussels trap sediments. While feeding on particles in the water, mussels selectively ingest some sizes and types of particles. The rest are wrapped in mucus and eliminated as pseudo-feces, which add substantial substance and nutrients to the surrounding sediments in the matrix of mussels. The result of all these processes is the provision of habitat and food for a very substantial number of species, such that the number of species in mussel-beds is very large (Lohse, 1993). The mix of species among the mussels will, however, be different from that outside a bed of mussels.

On rocky shores, many sessile species can function as ecological engineers, thus providing habitat for a range of species that may not otherwise live on the shore. These engineers are themselves patchily distributed, due to processes such as competition or predation, which, in turn, contribute to patchy distributions of those species that use them as habitat.

In soft sediments, ecological engineering can be very important. For example, large species can alter the habitat

considerably by bioturbation, irrigation, changes in nutrient fluxes, and so on. The distributions and abundances of many smaller species are therefore influenced by the activities of a few larger species, which have major impacts on the sediment (i.e., the habitat) itself.

There are also complications due to indirect interactions (reviewed by Wootton, 1993), where the outcome of competition between two (or more) species (say, A and B) influences the outcome of competitive interactions between one of them and yet other species (say, B and C). Indirect interactions have been categorized as being of two distinct types. The first are called “interaction chains,” where one species (A) directly influences abundances of a second species (B), which in turn influences numbers of a third species (C). Thus, A has an indirect effect on C, because of A's influence on B. The second type has been called an “interaction modification,” where species A directly influences a second species (B). A third species (C) influences the interaction between A and B. The difference between the two types is that, in the latter, species C has no direct influence on either of the other participants themselves (i.e., no direct effect on A or B).

As an example of an interaction chain, Kastendiek (1982) described the interesting case of the turfing red alga, *Halidrys dioica* (consider it to be species B), which outcompetes the alga, *Pterocladia capillacea* (species C), by growing over and denying it access to light (Figure 1).

Where there is a canopy of a third species (A), *Eisenia arborea*, however, the inferior competitor (C) survives well under the canopy and is able to “resist” competition from *H. dioica* (B). Thus, competition for light between *E. arborea* and *H. dioica* (i.e., A and B) diminishes the latter's capacity to grow well and to take over space that is occupied by inferior competitors (C), such as *P. capillacea*. As a result, competition by *E. arborea* over *H. dioica* prevents competitive overgrowth of *P. capillacea* by *H. dioica*.

Predation

A major process influencing the diversity of species on rocky shores is predation. Predation has three distinct influences. First is simply that where predators are sufficiently numerous or active, they may eliminate some species from areas of habitat. Thus, toward the bottom of rocky shores on the north-west coast of the US (Connell, 1970), several species of the whelk, *Nucella* (or *Thais*), feed on barnacles. Low on the shore, the whelks had sufficient opportunity (due to prolonged submersion by the tides) to eat all of the barnacles, thus eliminating them from such low areas and thereby reducing the diversity of sessile species there. At higher levels, in contrast, the whelks were less active, because they had a smaller period submersed during low tide in which they could find an item of prey and consume it.

The second influence of predation is indirect. The whelk *Morula marginalba* in southeast Australia consumes a variety of prey, including barnacles and small limpets, *Patelloida latistrigata*. It takes the whelks considerably longer to drill a hole through the shell of a barnacle than to eat a limpet; *M. marginalba* can consume *P. latistrigata* without having to drill a hole through their shells. Fairweather (1985) removed

Figure 1 Diagram illustrating indirect interactions involved in competition for space and light among intertidal seaweeds (Kastendiek, 1982). The kelp, *Eisenia arborea*, forms a canopy that provides shade and moisture during low tide. Under the canopy, the red alga, *Pterocladia capillacea*, can thrive. Elsewhere, it is overgrown and outcompeted by the turfing alga, *Halidrys dioica*.

limpets from some areas as they arrived. As a result, predation of small barnacles by whelks increased. This demonstrated an indirect effect of preferences and differences in the time taken to consume prey; the least preferred species (the limpets) took less time to eat than the more highly preferred barnacles. Where there were no limpets, the whelks turned their entire attention to small barnacles, with consequent increased mortality and decreased abundances of the barnacles. Note also that whether or not limpets arrived from the plankton also influenced the eventual outcome in terms of abundances of barnacles and, therefore, the local relative abundances and, thus, diversity of species.

The final major influence of predation is also indirect. Large generalist predators are capable of consuming most other species in any patch of habitat. As a result, they can have direct influences on the abundances of prey and can free space on the shore for species to be able to recruit. Space is often in short supply, causing the various sessile species to compete with each other for space on which to live and causing grazing species to compete for space over which to feed. If the generalist predator disproportionately consumes "winners" of competitive struggles for space, predation will have very important effects on the local diversity of species. The original example of this phenomenon, known as "keystone predation," was investigated by Paine (1974). The large starfish, *Pisaster ochraceus*, eats most of the other sessile and mobile animals on rocky shores on the west coast of the US. In some areas, the starfish preferentially eat mussels (*Mytilus* spp.). Mussels are, however, among the best competitors for space, being able to smother and grow over other species (see earlier). Predatory starfish continuously remove mussels, making space available for inferior competitive species that would otherwise be locally eliminated by overgrowth due to the mussels. In this case, the predators exert an indirect positive influence on a range of species of prey, resulting in there being greater numbers of species (i.e., greater species diversity) where there are predators than where there is none.

Any analysis of the processes maintaining local diversity is made complex by the fact that different types of indirect

interactions are not really mutually exclusive categories of ecological influences, as proposed by Wootton (1993; see [Competition and Facilitation](#)). For example, on shores in southeast Australia, the canopy-forming alga, *Hormosira banksii*, provides shelter from desiccation and heat stress for whelks, *M. marginalba*. The whelks come out from shelter to eat surrounding barnacles, *Chamaesipho tasmanica*. The algae are part of an interaction chain in that they provide habitat for whelks, which, in turn, decrease numbers of the barnacles. At the same time, the size of the algal canopy has been shown experimentally to influence the effectiveness of the whelks as predators (larger canopies are found with greater rates of predation on barnacles). Thus, the algae are also an interaction modifier of the process of predation by whelks on barnacles.

Physical Disturbances

Given that physical factors such as desiccation and wave action can have large and important influences on the abundances and diversity of species in intertidal habitats, it is not surprising that physical disturbances can influence diversity. Where disturbances are large or frequent, it is likely that more delicate species that are unable to withstand the physical forces will be unable to survive. They are either prevented from settling and becoming established in the first place or unable to complete their life cycles before a large disturbance kills them. It is expected under this model that there would be reduced diversity in more physically stressed habitats simply because of the direct loss of species due to disturbances. In contrast, where disturbances are small or rare, most, if not all, species can survive the rigors of the environment. Resources of space and food will then become critical and some species will disappear because of the superior competitive abilities of other species. Under these circumstances, diversity in physically benign areas will also be reduced below what is theoretically possible.

As a consequence of these two processes, it is anticipated that the greatest diversity should be found in areas of intermediate disturbance, such that competition for resources is

not too intense because there is sufficient disturbance to prevent all of the possible species from building up excessive abundances. At the same time, physical stress is not so great that some species are actually eliminated. This is the model of "intermediate disturbance" (Connell, 1978).

From this model, it has been predicted that in areas where physical disturbances can be increased or decreased in intensity or frequency, there will be predictable changes in diversity. For example, where disturbances are small, increasing their severity will cause increases in diversity as superior competitors are prevented from building up sufficient numbers to consume all of the resources needed by other species. If disturbances are increased even more, there will be a decrease in diversity.

Such predictions have been tested in several studies on rocky shores, with mixed success. Sousa (1980) identified patterns of diversity that were fairly consistent with the model, but the mechanisms operating were not as stated. Species were not lost by superior competition for space from other species. Rather, the life histories of the different species and the time taken to be able to recolonize disturbed areas were of greater importance. McGuinness (1987) identified the intermediate disturbance model to be an appropriate explanation for only some of the observed patterns of diversity that have been examined in intertidal boulder fields. Clearly, more work is needed to understand how and when the interactions of competition and disturbance lead to predictable outcomes in terms of the diversity of species.

Boulder Fields

Intertidal boulder fields form a very interesting habitat that forms part of rocky intertidal environments. Boulders have top surfaces that are exposed to waves and sunlight and that may be emersed during low tide. Underneath boulders, however, there is a very different sort of habitat – usually cool, moist, and dark. On shores affected by large waves, boulders are frequently overturned and moved. This alternately exposes each surface of the boulder to the light and causes the boulders to abrade against each other, damaging and killing many animals and plants living on them. These boulders support little biodiversity, mainly encrusting species that are resistant to harsh conditions or ephemeral species that rapidly colonize new habitat when it becomes available.

Boulders on sheltered shores, in contrast, are stable and support great diversity of animal and plant life. Different species are found on the tops of or underneath these boulders. Those on top are similar to those living on nearby rocky shores – after all, they are subjected to similar environmental conditions. Therefore, boulders may be covered with leafy and encrusting seaweeds, have patches of apparently bare rock or support large numbers of snails, limpets, and other common intertidal animals.

The species living under boulders are completely different. There are few leafy seaweeds, but there may be many kinds of encrusting seaweeds, which seem to thrive under dark conditions. There can also be patches of sessile animals – plate-like bryozoans, jelly-like masses of colonial ascidians or sea-squirts, encrusting sponges and the calcareous, and sandy tubes of different types of worms. These sorts of sessile

animals are not common on rocky shores, except in rockpools or crevices, or under ledges (Figure 2).

Many of the mobile animals living under boulders are rather specific to boulders – they tend to be rare or absent from other intertidal habitats. Many show very specific patterns of behavior that allow them to move quickly from one boulder to another if the boulders are overturned or moved into unsuitable conditions by large waves. Therefore, although chitons on rocky shores tend to be very slow-moving and inactive animals, those under boulders move extremely rapidly over the rock-surface or curl up and drop from the boulder as soon as it is overturned. This behavior returns them to the undersurface of the same or nearby boulders.

Intertidal boulder fields are potentially important habitats for the conservation of biodiversity. They often form rather small patches of habitat – especially when compared with sandy beaches, mangrove forests, or rocky shores, which are often continuous for many kilometers. They are also often scattered along the coast, with large stretches of other habitats between them. There are no data about how much interchange there is among populations in different boulder fields or how consistently species would recruit from other boulder fields if locally eliminated. Because many species living in boulder fields are relatively confined to these habitats, they are likely to be vulnerable to human activities that destroy or damage their surroundings, but recent work demonstrates that many species can colonize newly created boulder fields.

Finally, many species are extremely overdispersed. This means that each species tends to be crowded onto relatively few of the available boulders, with most boulders not being occupied by that species. Because different species are often found on different boulders, individual boulders support different suites of species. Patterns of biodiversity are therefore very complex – both within and among different boulder fields.

As yet, the processes that lead to these complex patterns are not well understood, but include such factors as the size and shape of the boulder, what stone it is composed of, where it is (e.g., depth of water, what substratum is beneath it), and the different wave conditions where the boulder field is located. In addition, there are complex interactions among the animals

Figure 2 The undersurfaces of intertidal boulders support numerous species of sessile and mobile animals, many of which are not found in other intertidal habitats. These include encrusting sponges, ascidians and bryozoans, numerous chitons and snails and starfish, sea urchins, and brittle stars.

and plants themselves (Sousa, 1980), causing complex changes to biodiversity depending on which species happen, by chance, to recruit to which boulders.

Mangrove Forests

In contrast to intertidal rocky shores and boulder fields, mangrove forests are dominated by trees. Unlike some other habitats containing many large plants – for example, subtidal kelp beds (Foster and Schiel, 1985), and terrestrial rain forests (Terborgh, 1992) – patterns of diversity in mangrove forests (i.e., variation in the numbers and types of animals and plants found from place to place or time to time) are not well documented (Hutchings and Saenger, 1987). This is particularly true for any measures of small-scale patchiness in diversity within individual forests. This contrasts markedly with other intertidal habitats in which patchiness of animals and seaweeds is relatively well described (see the discussion on rocky shores presented earlier).

This lack of good quantitative measurements of biodiversity in mangrove forests is due to many different factors. First, the plants that make up the forests are, themselves, not very diverse. Typically, they do not develop a complex structure of many species of canopy, understory, and ground cover, which could, in turn, support many different types of animals. Second, because mangrove forests normally grow on very sheltered shores, the vertical gradients of environmental conditions associated with tidal height are very strong (Hutchings and Saenger, 1987). There are also strong latitudinal gradients, causing very large differences between temperate and tropical zones in the types and diversity of trees that make up the forests. These are well documented elsewhere and are not discussed further here. Within any single mangrove forest, however, different species of trees typically live at different levels along the intertidal gradient, so that in any one place, even fewer types of plants are found.

The main factor that has led to a poor description of the distribution and patchiness of biodiversity in mangrove forests is, however, that most diversity is due to small invertebrate animals. This is, of course, true for many habitats where much of the biodiversity is “invisible.” In such habitats, appropriate sampling can clearly measure variation in diversity from place to place or time to time, but these sampling designs are inevitably complex and costly because they need to measure diversity at many different spatial and temporal scales.

The animals that make up most of the biodiversity in mangrove forests include many species of crustaceans, such as crabs and amphipods, small snails and bivalve mollusks, worms from many different phyla, insect larvae, and so on. Because these animals are generally very small and live on or under the surface of the mud, they are not readily visible without sampling small patches of mud, sieving the animals out of the sediment, and viewing them under magnification. The arduous work that this entails means that patterns in diversity are not well described for most mangrove forests.

In addition, because the types of plants found in mangrove forests often vary along the intertidal gradient, most studies of the distribution and diversity of animals have also described similar broad-scale patterns. Therefore, changes in the diversity

of snails, crabs, and other animals from the seaward to the landward edges of the forest tend to dominate the literature. There have been few descriptions of the small-scale variability or patchiness in this diversity within a shore level, although this may be the most important source of variation in diversity, as is the case on rocky shores. Some studies that have been carried out to measure small-scale patchiness in diversity in mangrove forests show that much of the variability in the diversity and abundances of these animals is at very small spatial scales (i.e., among patches of habitat centimeters or meters apart). It can also change unpredictably through time (Figure 3).

This sort of patchiness of diversity is not limited to small invertebrates that live in the mud. Many of the larger animals that spend their juvenile stages in mangrove forests, such as fish, prawns, and large crabs, show similar patterns. A survey of small fishes in patches of mangrove forests in Sydney Harbor showed that most of the variation in abundance and diversity was found at the scale of meters (i.e., from one net to another set in a small patch of mangrove forest). Variation from site to site (hundreds of meters apart in the same bay) and from bay to bay (kilometers apart) together accounted for less variability.

In contrast to rocky shores, there is little information about the processes that cause this small-scale patchiness in mangrove forests. This is due to the fact that, with few exceptions, mangrove forests have not been as well studied, particularly using well-designed, controlled field experiments.

The diversity of small animals living in sediments in any aquatic habitat is influenced by the range of grain sizes of the sediment itself. Larger species tend to be more common in coarse-grained sediments; small species are common among finer sediments. The range of sediment in any particular mangrove forest can vary from patch to patch because of such processes as differences in water currents around submerged objects (e.g., the bases of trees) or numerous biological processes, each of which also strongly and independently influence the patterns of diversity of the fauna.

In New South Wales (Australia), when feeding and burrowing, the mangrove crab, *Heloecius cordiformis*, creates mounds of coarser and drier sediments and flat areas of wetter and finer sediments (Figure 4; Warren and Underwood, 1986). Although not yet measured, it is likely that this activity directly influences local patterns of diversity, as has been shown for the burrowing behavior of soldier crabs in Tasmania (Warwick *et al.*, 1990). Other small-scale structures – for example, buried shells, the roots of the mangrove plants, worm tubes – are equally likely to alter patterns of diversity, although the importance of these small structures and the behavior of other animals as influences on biodiversity are not yet well documented for mangrove forests.

Sandy Beaches and Mudflats

Sandy beaches and mudflats tend to grade into each other along a continuum depending on the relative grain size of the sediment. Sandy beaches have rather coarse-grained sediments and mudflats are, of course, muddy, with fine-grained sediments. Both can occur on very sheltered shores, such as in estuaries, but mudflats do not occur on wave-exposed shores, where sandy beaches may be common (Brown and McLachlan, 1990).

Figure 3 Variability in the numbers and types of animals living in a mangrove forest in New South Wales, Australia. The animals were sampled in four sites along the bank of a river. Each site was sampled using four quadrats, placed 1–2 m apart. Each point on this figure represents the types and numbers of animals in each quadrat. The relative distance between two points indicates how similar the animals were in those two quadrats. Points close together represent quadrats containing very similar types of animals. Points far apart indicate that the quadrats contained very different numbers and types of animals. **Figure 3(a)** shows that when the animals were sampled the first time, the diversity of animals was highly variable from one quadrat to another. Quadrats in the same site (meters apart) showed similar amounts of variability in these measures of diversity as shown by quadrats in different sites. **Figure 3(b)** shows what the patterns looked like only three months later. Animals were more similar at the scale of meters (among quadrats in each site), but the sites appeared to represent a gradient along the river. This relatively large change in the pattern of diversity was not seasonal, predictable, or found in other nearby sites. It was mainly due to changes in the relative numbers of numerous small crustaceans.

Sandy beaches and mudflats have very few large plants, although heaps of decaying plant material, commonly known as beach wrack, can be found on the strandline. This material – decaying seagrasses, seaweeds, and kelps, which have been washed up by the waves – is rapidly decomposed by bacteria, fungi, and small animals, many of which are dependent on wrack for food. This activity ultimately releases nutrients back into the coastal waters (Griffiths *et al.*, 1983).

Sandy beaches and mudflats appear at first glance to resemble deserts – there are often few animals to be seen, other than birds and a few crabs. The birds are generally visitors to these shores, feeding along the shoreline or over the extensive flats during low tide, but spending the rest of their time elsewhere. There are relatively few animals high on the shore,

mainly semiterrestrial species, such as ghost crabs that spend the day in burrows above the level of high tide, coming out at night to feed. Nevertheless, despite first appearances, there is diverse life lower on the shore. As is the case in mangrove forests, however, most of the animals live under the sediments.

Very small animals live in the tiny spaces among the grains themselves. These include unicellular and multicellular animals from many different phyla. Many of these very small animals resemble juveniles of larger species. Many are also extremely simple. For example, although multicellular, they may only consist of a few cells and lack structures – such as limbs, kidneys, or a circulatory system – relying on exchange of substances through the body wall to acquire oxygen or eliminate waste (Brown and McLachlan, 1990).

Figure 4 The crab, *Heloecius cordiformis*, and its burrows are more numerous on mounds of sediments than in the flatter patches of habitats in between the mounds. These mounds are created by the crabs themselves.

The larger animals living under the sand or mud either construct and maintain complex tubes or burrows or simply move through the sediment without leaving any structure behind them. On sandy beaches exposed to relatively large waves, the sediment is continually reworked by wave action. Most animals living in these habitats do not construct tubes or burrows because these are likely to be destroyed. Instead, they remain relatively deep in the sediment or tend to have mechanisms whereby they can rapidly burrow back under the sediment if exposed. Mole crabs have paddle-shaped limbs and can burrow extremely quickly during the time available between waves. Similarly, many bivalves have an extendible, mobile foot, which rapidly digs and anchors into the sediment and then contracts, pulling the bivalve under the sediment in only a few seconds.

Because mudflats tend to be very extensive and not steeply sloping, they usually remain quite damp during low tide. Many different species of worms, crustaceans, mollusks, and so on can be found in these habitats. Although some simply burrow through the sediment, feeding on detritus and particles attached to the grains, others live in semipermanent tubes or burrows. These can be very complex. Some burrows of crabs have many entrances and exits and are connected together in a complex underground labyrinth. Some animals living in burrows emerge to feed on the surface of the mud itself during high tide or at night. Other species remain in the burrow, but they may have long tentacles that are spread over the surface of the mud to pick up particles of food. Animals inhabiting burrows that feed on particles in the water often have modified limbs or other appendages, which can create currents of water through the tubes, pulling in the food with the water current. They also have very elaborate filters, which sieve the particles of food out of the water. These filters are modified legs, mouthparts, gills, or other organs.

Despite the fact that sandy beaches and mudflats are very common intertidal habitats, their patterns of biodiversity are not particularly well known. Available data suggest that, like most other intertidal habitats, they are extremely patchy and variable through time. The numbers and types of animals differ from one patch to another only a few meters away. These

patterns are caused by the different species responding to subtle changes in the sediments themselves, to local disturbances such as feeding by fish, which creates depressions in the mud, and to other animals living in the sediment via inter-specific processes, such as competition or predation.

Some species have rather aggressive behavior that spreads them out, presumably to ensure adequate food for all. Other species tend to aggregate and can create large patches of tubes or burrows, altering the sediments around them. These sorts of processes inevitably alter the small-scale local patterns of diversity, but there is very little information on how such processes may operate. Of course, as described earlier, such processes modify the initial patterns of diversity, which are established by the differential recruitment of species among different patches of habitat.

Measurement of Biodiversity in Coastal Habitats

Methods for and interpretations of measures of biodiversity in coastal habitats have proven complex. As reviewed by Gray (2000), the simplest measure – the number of species in any area – does not describe the structure and variation in assemblages. For this, measures are needed that can collate information on the types of species present (the composition of an assemblage) with information about their relative abundances. Many indices have been used (see Magurran, 1988). One of the most widely used is the Shannon–Wiener index:

$$H' = - \sum_{i=1}^s p_i \log_2 p_i$$

where p_i is the proportion of species i in the entire sample. Measurements of diversity in a single sample have been described as “point diversity.” Diversity in a set of replicate samples from the same habitat is “alpha diversity.” Comparisons from habitat to habitat, for example, along an environmental gradient uses measures of “beta (or between habitat) diversity.” This is the combined diversity across a set of alpha diversities. There are also larger scale measures, such as “gamma diversity,” which are measured across larger spatial areas, such as an entire coast-line.

There are serious problems of scale in these considerations. For example, a rocky headland could be a relatively large area; thus, diversity measured across it would be gamma diversity. Within the area, there are different habitats such as rock pools, algal beds, boulder fields, and so on. In each of these, samples would provide measures of alpha diversity. Beta diversity would measure the diversity in, say, algal beds along a gradient of increasing exposure to waves.

Suppose, instead, that the study was a series of headlands along the biogeographical gradient from south to north along a coastline. It is now likely that the diversity measured in a set of randomly taken replicates from one headland would be considered to be alpha diversity. That from the set of headlands would be beta diversity. Thus, whether or not a sample allows measurement of alpha or gamma diversity is entirely dependent on the spatial scale being examined. It is clearly important to define the hypotheses being tested very carefully so that only the relevant scales of habitats and sample areas are examined.

Another major difficulty in measures of diversity is that the number of species found is almost always dependent on the size of the sample examined or the length of time spent searching for individuals throughout the habitat. This is inevitable because of two distinct aspects of the patchy distributions of species. First, rare species are not going to occur very often in any sample and will often be missing from small samples. Considerable space needs to be covered to be sure that the rare species are actually encountered. Imagine a comparison of the animals in two habitats, which each have one hundred species in them. If, in one habitat (A), many more of the species are present than is the case in the other habitat (B) and similarly sized small samples are examined from each habitat, there will be apparently fewer species in Habitat A than in B. This is, however, an artifact of sampling.

A second reason for there being inevitable differences in the numbers of species seen in two samples where one is much larger than the other is due to the potential heterogeneity of habitats in the area studied. Suppose that the number of species is recorded in samples totaling 4 square meters of habitat in one area and 8 square meters in the other habitat. The latter sample would normally be expected to contain more species if there are many subhabitats in the area sampled. Thus, on rocky shores, clumps of seaweeds, small rock pools, patches of mussels, and so on may be scattered at scales of tens of centimeters. Each of these subhabitats probably contains several different species, in addition to "cosmopolitan" species found throughout the entire area. As a result, the larger area examined in samples from one habitat will encompass more different patches and therefore contain more species than would be found if a smaller area were examined.

There exist techniques to compensate for differences in the size of samples from one habitat to another. One of the most commonly used is called rarefaction, but this is known to have serious problems of overestimation of numbers of species in small samples (Fager, 1972). A superior alternative is to take random smaller samples from the largest, to match the size of the smaller samples from the other habitat. Such random samples can be used to provide reliable estimates and estimates of error associated with the number of species expected in smaller samples. Comparisons between the two habitats then consist of comparisons of the entire sample from the habitat that was sampled with smaller samples and the randomly determined estimates from the other habitat (reviewed by Gray, 2000).

Some multivariate methods are widely used to compare the diversity of species from one area or habitat to another. These operate on the principle that the abundances or biomasses of every species can be recorded from a series of replicate sample units (cores, grabs, quadrats, etc.). This produces a matrix of species by replicates for a sample from each habitat or area. The difference from any one sample unit to another can then be calculated across all of the species. One popular measure of such difference is the Bray–Curtis dissimilarity index (Clarke, 1993). This is calculated as follows:

$$D_{j,k} = \frac{\sum_{i=1}^s |X_{ij} - X_{ik}|}{\left(\sum_{i=1}^s X_{ij} + \sum_{i=1}^s X_{ik} \right)} \times 100$$

where $D_{j,k}$ is the dissimilarity between sample units j and k , X_{ij} is the abundance of species i in sample j , X_{ik} is the abundance of species i in sample k , and s is the total number of species found in the two sample units. If j and k come from the same sample, this is a measure of variation among units within a sample. If j and k come from two different samples, D is a measure of dissimilarity between the two samples. Because there are replicate measures, there is a sample of measures to estimate variation within each of the two samples and between the two samples. Statistical tests can then be carried out to determine the likelihood of there being more difference between two samples than expected by chance, given the variability within the two samples (Clarke, 1993).

Similar procedures are now being used widely in tests of the effects of environmental impacts and in many ecological studies to measure the diversity of animals in different habitats, where diversity is made up of the composition of species in any habitat and their relative abundances (many are summarized in Anderson *et al.*, 2008). Recent advances in these analytical techniques have increased the range of experimental designs for which they can be used (Anderson, 2001), and there are now many descriptions of complex patterns of natural variability in assemblages across a variety of spatial scales, and from time to time. More intensive sampling can yield large enough samples for independent measures of dissimilarity at different scales, allowing tests of more complex hypotheses about variability in diverse assemblages (Underwood and Chapman, 1998). Although very useful in measuring diversity, these analytical techniques do not, however, provide any clear understanding of the various physical and biological processes that cause such variations in diversity. To understand this, more knowledge is still needed of the ecological processes influencing the individual species that make up diversity in any place and at any time.

Can Intertidal Biodiversity Indicate Ecological Function?

Although it is clear that "biodiversity" covers many levels of variability, from genetic to population diversity within species, from diversity among species to diversity among habitats or ecosystems, the most common perception of biodiversity is still simply the numbers and types of animals and plants in different areas. Therefore, the importance of biodiversity has often focused on terrestrial habitats, the consensus of opinion being that there are more species on land than in the sea (Gray, 1993). Nevertheless, at different levels of organization, marine systems are more diverse – for example, there are more phyla in the sea than found on land. In addition, marine species appear to have more genetic diversity than related terrestrial and freshwater organisms. This suggests that they may be less vulnerable to processes that reduce genetic variation, although there is increasing concern that many near-shore aquacultural practices, including culture of fish and bivalve mollusks, are decreasing the genetic variability of natural populations.

Although many small marine invertebrates still remain to be identified and described, it is generally held that most diversity in the sea is of benthic organisms. There are many more

species of animals and plants living on or in close association with the sea floor, rocky reefs, and others, than living in the water column itself. This is probably related to the diversity of different benthic habitats. There is still controversy about the relative importance of deep-sea habitats and coastal habitats to benthic diversity – controversy arising from the fact that these habitats are so poorly described that the general patterns of biodiversity across large areas of marine habitat, even nearshore and intertidal habitats, are largely guesswork.

At whichever level biodiversity is examined, however, understanding patterns of biodiversity is essential to understanding the role(s) of diversity in the maintenance of different ecological functions. By functions, we mean such processes as maintaining diversity itself, recycling nutrients and chemicals among organisms and their surrounding habitat, and maintaining appropriate habitat for adequate food, shelter, and so on. Because patterns of biodiversity are complex – biodiversity varies at many spatial scales from centimeters to hundreds of kilometers and changes predictably and unpredictably among days, weeks, seasons, years, and eons – the role of diversity in maintaining the functioning of individuals, populations, assemblages of species, and habitats will also be necessarily complex.

Relationships between biodiversity and the persistence of successful ecological functioning may be described by quite different theories (see the review by Hooper *et al.*, 2005). First, there may be considerable redundancy of species, so that many species may be lost without impairment of function because other species simply take on their roles. This may be common in assemblages of very similar and small species, such as the many species of amphipods that live in some algal mats, or the many species of small burrowing worms in sediments. There must obviously be a limit to this; not all species can disappear and the ecology of the assemblage still persists. A second view is that many species may contribute to any ecological function, but the system may withstand loss of these species until a crucial limit is reached, after which there will be a rapid and inevitable degradation of function. The third view, called the idiosyncratic response, has been shown to be most likely in intertidal systems that have been examined. There is loss of function with loss of species, but this is variable and unpredictable because of the complex patterns of abundance and interactions among the various component species.

Most of the experimental tests of the relationships between biodiversity and ecological function have been carried out in terrestrial systems. The results of different experiments are not clear-cut, and there is considerable controversy about their designs and the ways in which they have been interpreted (Huston, 1997). Because of the fundamental differences in the ways in which different processes operate between marine and terrestrial habitats, it is unlikely that the results of such experiments, even if not controversial, could be applied to marine systems. Therefore, it is essential that the importance of biodiversity to the well-being and persistence of coastal habitats be tested experimentally in marine habitats.

Experiments have generally examined the removal of species from assemblages or the creation of artificial assemblages by the addition of different numbers and types of species. Despite differences between marine and terrestrial systems,

recent research has indicated some commonality in changes to ecological functioning when the numbers of species in assemblages are altered. Frequently, the number of species matters less to the maintenance of some important ecological functions than does the identity of the species in an assemblage. Some species appear to have large and important effects, whereas many others have little measurable effect.

Nevertheless, although loss of such large and important species can alter many ecological functions, experiments have shown that not all changes were as predicted from current ecological understanding. This shows that there is still much to learn before the effects of changes to the diversity of even ecologically important species can be understood.

To date, the functional role of marine biodiversity at large scales has mostly focused on off-shore processes. For example, people are concerned about the diversity of plankton and its role in large-scale processes, such as commercial fisheries or atmospheric levels of CO₂ and O₂. In coastal habitats, most emphasis has been on the role of diversity in maintaining ecological function and has focused on single species or suites of similar species. Therefore, there is concern about the loss of large filter-feeding bivalves in estuaries and bays because the large numbers of these animals were considered to filter all of the water in the estuary in only a few days. In areas where populations have crashed, the water has become more turbid and is now occupied by different types of animals than was the case in the past. Similarly, certain large predators or grazers on intertidal shores or shallow reefs appear to play a pivotal role in maintaining patterns of biodiversity by selectively removing competitively dominant sessile animals or plants with their associated species, thereby providing space for a host of other organisms that thrive under the altered conditions (see the earlier discussion on keystone predators).

“Ecological engineers” (Lawton, 1994) have also received considerable attention because of their roles in altering the physical environment, creating habitat, and changing the availability of resources to other species. Many coastal animals are ecological engineers – the most obvious of which are corals that may develop into large reefs – a unique and very diverse habitat totally dependent on the corals themselves. Other lesser-known examples include burrowing bivalves and crabs in salt marshes, which can alter drainage, sedimentation, and erosion in addition to having direct impacts on other animals or plants that they may eat or for which they may be an important source of food. Some intertidal animals form habitat for a range of other species. Therefore, mussels of the genus *Mytilus*, provide habitats for more than 300 other species of animals and plants on intertidal shores in Washington, in the US (Suchanek, 1992).

Mangrove trees stabilize sediments, modify shorelines, prevent erosion, and provide habitat for the juveniles of commercially exploited fish and shellfish. Many studies examining the relationship between structure and function in mangrove forests have focused on changes in the number of trees, especially in areas where they are cut down for firewood.

There has, however, been little consideration of the role of the actual biodiversity of such habitats – the mud-dwelling bacteria and small animals – on the well-being of the trees themselves, or, indeed, on the maintenance of the habitat itself. Unfortunately, as described earlier, little is known of this

Box 1 Despite the fact that there is no unambiguously accepted list of what is meant by the values of biodiversity, many values are cited as being important.

Evolutionary value. This includes genetic diversity that may allow organisms to persist or change in response to localized threats to diversity. This may be very important in intertidal and near-shore coastal habitats, where humans tend to cause most damage to marine habitats.

Ecological value. A naturally functioning habitat with its full complement of biodiversity is necessary for studying and understanding ecological patterns and processes. This understanding is, in turn, considered essential for the persistence of life on earth in the face of humanity's alteration to and degradation of the natural world.

Economic value. There are or may be species of direct economic value. On intertidal shores, this includes plants and animals collected or cultured in fisheries, mangrove trees exploited for firewood, and so on. Habitats that are used for recreation may also have economic value. For example, a wetland with diverse species of birds can have economic value if bird-watchers are prepared to pay to access it.

Aesthetic value. Natural habitats are sometimes perceived to have value simply because they exist. This is also sometimes called "existence value."

Ethical value. There is argument by many sections of society that all biodiversity has ethical value, that is, we, as human beings, are ethically bound to protect biodiversity. This argument comes to the fore when decisions are being made about the rights of humanity to eliminate diseases and other pests from the earth.

biota, other than the fact that it is variable, unpredictable, and complex. Because the species are poorly described and even more poorly understood, it is generally accepted that there is considerable redundancy in the system. Therefore, it has been assumed that, if the larger plants are looked after, the small invertebrate animals and the functioning of the habitat will look after itself.

The same is true of all intertidal habitats. Most ecological functions are thought of in terms of general, widespread, and large-scale processes (e.g., the cycling of nutrients throughout a mangrove forest or the maintenance of food webs across a rocky shore). Yet, the fauna and flora that make up most of the diversity and that maintain these ecological functions are variable and patchy and change unpredictably through time, often at very small and localized scales. The scales at which ecological structure (the species) and ecological functions (many of the processes) are measured are often quite different. It is therefore difficult to relate the stochastic variability that we see in ecological structure with what is often perceived as the predictability in measures of ecological function. It is increasingly important that we measure structure and function at a similar range of scales before we will be able to understand the role of natural patchiness in biodiversity in ecology. This is not yet widely done, but is crucial if we are to be able to conserve functioning habitats in an increasingly altered world.

What Services Does Intertidal Biodiversity Provide?

Consideration of the relationships between the diversity of species and functioning of ecological systems leads very rapidly to consideration of any "values" of biodiversity. Because biodiversity is not well described (i.e., the threats to it are poorly understood and probably variable from place to place and habitat to habitat), there is still considerable controversy about perceived value(s) of biodiversity. This is specifically true for most coastal habitats, especially those on temperate coasts, which have not received as much attention from the media and celebrities as have habitats such as coral reefs or tropical rainforests.

There are many so-called values to biodiversity, some of which are discussed in **Box 1**. Whatever terms are used, however, they tend to fall into two main categories. Ecocentric values are those associated with the well-being of the animals and plants themselves (i.e., they are focused on maintaining

the full range of functioning ecological processes). They include such terms as ecological value and evolutionary value (see **Box 1**). Anthropocentric values, in contrast, are centered on humanity and the role of diversity in maintaining or improving human lifestyles. These obviously include a range of values, based on our perceived moral obligations, our ideas of the sort of world that we want to live in, and obvious economic returns from our exploitation of coastal resources.

In contrast to many terrestrial habitats, nearshore coastal habitats, including nearly all intertidal areas, are generally conserved for anthropocentric values, rather than ecocentric values. Following traditions lasting hundreds of years, the sea is still largely regarded as a larder to be plundered rather than a unique set of habitats to be conserved. Apart from certain coastal wetlands, which can support large populations of wading birds, most intertidal habitats do not abound with large charismatic megafauna. Therefore, although they may contain threatened species, these are unlikely to attract media attention.

Although large areas of mangroves can be extensive, diverse, and very interesting forests, they are still generally valued for their economic returns – provision of firewood, habitats for juvenile commercially exploited fishes, sites for aquaculture, and, unfortunately in many countries, prime real estate for reclamation. Similarly, rocky reefs, mudflats, estuaries, and so on are generally considered important for what direct economic value they can provide humanity.

The loss or degradation of nearshore habitats goes largely unseen because the biota that live in them are small, cryptic, and unknown. Yet, they are incredibly diverse and in many parts of the world, make up a large amount of the endemic fauna and flora. Most of these organisms do not have commercial value. As long as these coastal habitats continue to be considered valuable mainly with respect to the direct economic services that they provide to humankind, there will be little initiative to carry out the research and impose the necessary management to conserve this diversity.

Conclusions

The management of biodiversity in intertidal coastal habitats needs a different approach from that used in terrestrial habitats. Except for species that are considered to play a key role in local ecological processes, it is unlikely to be useful to attempt

conservation on a species by species level. Exceptions are the so-called keystone species or ecological engineers, which were discussed in some detail earlier. Either these species provide habitat directly or their activities serve to enhance local diversity because of their elimination of competitively dominant species. For the most, however, emphasis on conservation of individual species is unlikely to be profitable.

First, for most species, we know too little about their requirements for habitat, food, and so on to be able to impose sensible managerial options. Second, we know too little about their natural patterns of variability in time or space to be able to evaluate whether any managed populations are persisting with anything like their natural patterns of abundance. Third, we certainly know too little about their interactions with other species to know which are essential to their continued well-being and which are not (i.e., which suite of species to try to conserve). In many cases, it has so far proven impossible to determine the geographical range of habitat occupied by a breeding population of intertidal animals, the extent to which there is interchange from one population to another, or the sources of recruits to any area that must be conserved.

Management of coastal biodiversity will better be focused on habitat. Removing or reducing disturbances to patches of mangrove forest, rocky shores, mudflats, and beaches is one of the more feasible and cheaper options – it is usually easier to prevent access to areas than to try to control people's behavior once they are in them. The fauna and flora will then be left to do the best they can under the circumstances. Fortunately, many species living in shallow-water, marine habitats are able to deal with many disturbances to their habitat, as long as these are neither too frequent nor too extreme. Evidence suggests that many can relatively rapidly recolonize areas once any disturbances are removed; such areas can then develop what appear to be functional ecological systems. Whether all species return to such habitats is not known because it is generally not known what species were there before the disturbance.

Nevertheless, there is obviously a need for more research on interactions among species wherever possible, so that keystone or engineering species can be identified. Where possible, management that will conserve these directly is likely to conserve those species that are dependent on them. Therefore, legislation that protects rocky shores from foragers removing mussels and other large shellfish will not only protect the targeted species but also a diverse range of other animals and plants. There is little chance that these could be protected on a species-by-species basis because too little is known about any individual species to mount a case for its protection.

Finally, with increasing understanding of the landscape ecology of coastal habitats and how "intertidal landscapes" interact, conservation of intertidal biodiversity is probably best within a mosaic of patches of different habitat. There is considerable debate about the value of few, large versus many, small reserves for conservation of terrestrial species. Which may be best is unknown for marine habitats and, in any case, there is no reason why what suits one species or set of species will suit another. The best strategy will probably be to hedge one's bets and try a range of different procedures. Therefore, with the current lack of understanding, conserving patches of

habitat of different sizes and shapes, set at different distances apart, and subjected to as wide a range of environmental conditions as possible, will probably be the safest option until we know a lot more about our intertidal biodiversity.

Clearly, our understanding of the processes that influence and change biodiversity is increasing at a satisfactory pace. Our ability to use these insights in the planning and management of conservation is, however, more limited. The natural variability due to numerous processes and the large ranges over which larvae seem to disperse combine to make predictions difficult. The urgent tasks for coastal systems in response to threats due to coastal development, aquaculture, disposal of wastes, and potential rises in sea level require more understanding of the scales of variability in the distributions and abundances of coastal species.

Glossary

Ancient lakes Lakes with a persistence of more than 100,000 years are called long-lived or ancient lakes.

Eutrophication The process of enrichment of a water body due to an increase in nutrient loading.

Species flocks An aggregate of closely related species that share a common ancestor and are endemic to a geographically circumscribed area.

Broad Characteristics of the Biodiversity in Lakes and Ponds

Freshwater habitats are widely considered to be transient in time and space in comparison with both terrestrial and marine habitats. This is true for many lakes and ponds. However, depending on the origin of lakes there are great differences in the nature and the diversity of their biota. Three broad categories of lakes may be recognized:

1. *Lakes and ponds that are permanently or frequently connected to large river systems.* This category includes river-lakes (i.e., Lake Geneva) or lakes that are part of a large floodplain system such as “varzea” lakes. In these lakes, exchanges of flora and fauna occur with the main river system so that their biota is usually greatly similar to the biota of the river system itself with the exception of a few species adapted to still waters. Many endoreic lakes (Lake Chad, Aral Sea) also belong to this group.
2. *Isolated lakes with a limited drainage system.* The biota of the lakes in this category has evolved in isolation from others for a more or less long period of time leading to speciation and endemism when the period is long enough. The associated ice ages at higher latitudes and altitudes were the phenomena that created most of the lakes in existence today. Therefore the great majority of existing lakes (around 10,000 exceeding 1 km² in extent) are geologically very young and occupy basins formed by ice masses or glacial erosion after the retreat of continental ice sheets some 10,000 years ago. All such lakes are expected to fill slowly with sediment and to disappear in the future, along with any isolated biota. Compared to ancient lakes, they acquired their fauna and flora via the rivers that supply them with water as a result of runoff in their basin and

from aerial transport by wind or animals. Only a few existing lakes are known to be much older, and most of them occupy basins formed by large-scale subsidence. They may date back at most 20 million (Lake Tanganyika) or 30 million (Lake Baikal) years. These so-called ancient lakes are of particular interest for biodiversity because they exhibit a rich endemic fauna for several major groups of animals. There is also good evidence that some extinct lakes were also very large and long-lived under different climatic and tectonic conditions.

3. *Temporary lakes and ponds whose water budget is controlled by the climate regime.* The fauna and flora in these lakes exhibit special biological adaptations to seasonal drying.

Origin and Peculiarities of Freshwater Biota

It is thought that the early evolution of all the major animal phyla took place in the sea. Most phyla are predominantly marine and benthic: 32 phyla are found in the sea with 11 exclusively marine, whereas 14 are represented in freshwater and only 12 are found on land (May, 1994). Compared to the sea, freshwaters are deficient in major taxa and there are no uniquely freshwater metazoan phyla. The osmotic challenges of life in freshwaters probably discouraged invasion of the habitat by many marine invertebrates. It explains probably the tendency in freshwater invertebrates for larger but fewer eggs than in marine relatives: they must eclose with fully developed osmoregulatory capacities to be at a more advanced stage to cope with the highly dilute surrounding.

Another difference between the species richness of marine and freshwater zooplankton derives from the necessity of diapause or other resting mechanisms as a condition for

persistent successful radiation in freshwaters (Lehman, 1988). Freshwater invertebrates developed anabiotic devices: special resistant eggs, cysts, and other resting stages that are produced to tide the animal over periods of desiccation, extreme cold, heat, anaerobic situations, lack of food, and other adverse conditions. In addition to withstanding unfavorable conditions, resistant stages have the further function of making overland transport and geographical dissemination possible. Without such a function, colonization of freshwater areas would be slow and difficult in the discontinuum of isolated lakes and ponds.

The Latitudinal Gradient

It is usually assumed that species diversity increases from high to low latitudes for most of the major groups of plants and animals and that highest values occur at low latitudes. Indeed, the diversity of marine plankton decreases from low latitudes to high ones, so that tropical and subtropical ocean waters exhibit rich diversity of zooplankton whereas Arctic and Antarctic waters tend to be dominated by copepods and euphausiids. In freshwaters however, the latitudinal trend in species richness is the opposite. Tropical lakes have abbreviated zooplankton faunas compared with temperate locales (Fernando, 1980); they are depauperate in large-bodied species of copepods and Cladocera, and limnetic rotifers are likewise poorly represented.

It could be assumed that the associated ice ages at higher latitudes and altitudes were the phenomena that created most of the lakes in existence today. They are therefore very young compared to ancient lakes, and they acquired their fauna and flora via the rivers that supply them with water via runoff in their basin and via aerial transport by wind or animals.

For fish, the species richness is actually smaller in north temperate lakes of glacial origin than in long lived lakes from tropical areas. At least the endemism is much lower in temperate lakes than in tropical lakes.

Dumont (1994), in a review of the species richness of the pelagial zooplankton in ancient lakes, provided also evidence that these water bodies have simple pelagial communities. Among 14 pre-Pleistocene lakes across the world, at least one Cyclopoid copepod species is present, often in the genus *Cyclops* or *Mesocyclops*, a group of microraptorial species feeding on rotifers, small Crustacea, and immature stage of other copepods.

The number of species regularly found in the pelagic plankton of ancient lakes (pre-Pleistocene) varies from 3 (Lake Tanganyika) to approximately 15 to 20 (up to 5 copepods, 5 cladocerans, 10 rotifers) in Lakes Victoria, Biwa, and Titicaca. In contrast, "young" lakes may have up to 10 species of copepods, 10 of Cladocera, and 10 to 15 species of rotifers occurring together. In the oldest lakes (Baikal, Tanganyika), which also happen to be the deepest, this simplification has gone extreme and the food web reduces to a linear chain.

The question has been raised as to why Cladocera have been almost completely eliminated from some ancient lakes such as Tanganyika, Baikal, and even Malawi (Dumont, 1994). They are able to eat both large items and microplankton and seem all but competitively inferior to other species for food

acquisition. Predation had been advocated as a possible cause. In clear-water lakes such as Tanganyika and Baikal, visual predation by fish is more effective than in turbid lakes, and large clumsy swimmers like big *Daphnia* are likely to be preyed to extinction before the relative small transparent, agile swimmers like the Calanoids. An experimental demonstration of this hypothesis has been the disappearance of all Cladocera from the pelagial of Lake Kivu, within a decade, after the introduction of the zooplanktivore clupeid *Limnothrissa miodon*, native from Lake Tanganyika (Dumont, 1986).

Vertical Distribution in Lakes

Aquatic organisms are not evenly distributed along depth. Water characteristics are relatively uniform in shallow lakes, which are mixed by winds. However, deeper lakes exhibit patterns of vertical gradients for temperature and light. Briefly speaking, the lake is divided by a thermocline into an upper layer, the epilimnion, and a lower layer, the hypolimnion. Life occurs in the oxygenated upper layer while the lower layer is deoxygenated. In most stratified lakes therefore, biota is very depauperated, except for bacteria, below a few 10 meters in depth. There is an exception, Lake Baikal, which is the deepest lake in the world with a maximum depth of 1620 m. The mechanism of mixing of the deep water zone is still not completely understood, but the entire water column is well oxygenated. Life for fish and invertebrates is therefore possible from surface to maximum depth, which is exceptional for freshwater systems. Lake Baikal is therefore unique among inland systems to the study of bathymetric segregation and includes some of the deepest occurring freshwater animals. Among fishes, the family *Abyssocottidae* contains 20 species distributed throughout the depths of the lake. Species of the genera *Abyssocottus*, *Cottinella*, and *Neocottus* are adapted to the deep water way of life in that they do not occur above 400 m, the size of the eyes is reduced, and they are physiologically adapted to resisting high pressures (Sideleva, 1994).

The discovery of a deep sea hydrothermal fauna in the 1980s was a surprise for marine biologists. Similarly, hydrothermal vents have been discovered in Lake Baikal, at a depth of 440 m on the sediment floor of Frolikha Bay (Crane *et al.*, 1991), at the foot of an east-west trending fault. Photographs reveal that the center of the vent field is covered by a near-continuous bacterial mat. A white sponge encrusts small cobbles at the periphery of the vent field. Coiled gastropods and whitish translucent amphipods are found among the sponges and on the sediment at the edge of the bacterial mat.

Relationship between Species Richness and Area in Lakes

Community ecologists used to compare isolated freshwater systems to biogeographic islands. The relationship of species number to area containing those species is a well-known empirical observation, and a power function is widely used to describe this pattern mathematically: $S = cAZ$, where S is the number of species, A the area, Z the slope of the regression line, and c a constant. It can also be expressed as $\log S = c + Z \log A$.

The effect of lake size on species richness of invertebrates has been demonstrated. For crustacean zooplankton, species richness is also significantly correlated with lake surface area (Dodson, 1992). The species area curve for North American lakes is statistically different from and steeper than the corresponding European curve (slopes, respectively, 0.094 and 0.054). The log species richness is also correlated to log of the average photosynthetic flux per cubic meter and log number of lakes within 20 km of the target lake. For 66 North American lakes, the three variables can be combined in a multiple linear regression model, which explains 75% of the variation in log species richness (Dodson, 1992).

Species richness of aquatic birds also increases with lake size. In Swiss lakes, the species number increase steeply with lake size up to 50 km² and species richness depends more closely on lake area in fish eaters and diving ducks than in dabbling ducks (Suter, 1994). Actually lake size explains 70 to 85% of the variation of abundance and species richness in fish eaters and diving ducks but only 64% of species richness in dabbling ducks. In Florida lakes, bird species richness was also positively correlated to lake area and to total water column phosphorus concentration value (WCP) for each lake. The multilinear $\text{Log (species richness)} = 1.12 + 0.56 \text{ Log (Lake area)} + 0.12 \text{ Log (WCP)}$ and accounts for 77% of the variance in species richness (Hoyer and Canfield, 1994).

Morphometry and Species Richness

The species diversity in a lake is a function of the diversity of habitats: the more ecological niches in the lakes, the more species may be expected. The lake's morphometry is basic to its structure: deep, steep-sided lakes do not offer as many biotopes as shallow, flat lakes. For the latter, most of the lake bottom may be colonized by plants and animals (the benthic flora and fauna), while in deep lakes, only a small part of the lake bottom is colonized. Generally speaking, deep lakes are dominated by planktonic organisms, which are floating or weakly swimming organisms, usually associated with suspended particles. In shallow lakes, benthic organisms are dominant and the heterogeneity of lake bottom, as well as the development of macrophytes, may increase the diversity of benthic species.

Evaluating Biological Diversity

Despite the efforts of taxonomists, a good estimation of the total number of species occurring in freshwater lakes and ponds does not exist. We shall provide here some recent findings about aquatic biodiversity.

Diversity of Plankton and Microbial Loop

Three major size classes are usually recognized in pelagic plankton: microplankton (20–200 µm), nanoplankton (2–20 µm), and picoplankton (0.2–2.0 µm). In the late 1970s, phototrophic picoplankton was discovered in great abundance in both marine and freshwater ecosystems. However, identifying picoplankton causes considerable taxonomic problems

due to the very small sizes of these organisms. We do not know how many bacterial species exists in the world, because bacteria cannot be differentiated under the microscope; we do not even know the right order of magnitude. A new way of classification has been proposed, based on the sequences of ribosomal RNA that led to a phylogenetic classification of bacteria. It is becoming apparent that the genetic diversity among bacteria is much wider than that among the animals and plants.

Most heterotrophic nanoplankters are small (2–5 µm), colorless flagellated protists. They grow at about the same rate as bacteria and are capable of consuming the entire bacterial production. Meanwhile, they regenerate significant amounts of nutrients and serve as prey for micro- and mesoplankton.

The importance of bacteria and protozoa activities in the trophic structure of lacustrine food chains has been largely underestimated in the past. The major role played by microorganisms in controlling energy and nutrient fluxes is now better understood following the discovery of the microbial loop and its role as a source or a sink for carbon and energy flow to higher trophic levels in pelagic systems. We know now that these microorganisms can control major fluxes of energy and nutrients. In some cases, 50% of the photosynthetic production does not pass directly to higher trophic level but is diverted into a microbial loop where nutrients are rapidly remineralized and fed back to the dissolved inorganic pools.

Diversity in Freshwater Sediments

About 175,000 species of organisms associated with freshwater sediments have been described, but the true number is much higher than this (Palmer *et al.*, 1997). The number of species in most taxa can scarcely be estimated and global estimate of microbial diversity remains controversial. For example, some specialists estimate that there are hundred of thousands of aquatic nematodes and only a small percentage of these have been described. Rotifer species diversity is also poorly known for freshwater sediments, but it is estimated that there are thousands of undescribed species.

Most freshwater sediment species are small and concentrated in the upper sediment layers. Availability of light limits the development of plants and photosynthetic bacteria, which are therefore scarce or absent in most sediments. Moreover, oxygen level may influence species richness and the number of species is low in anoxic waters (see Table 1).

Diversity in Fish

Presently, 25,000 fish species have been described. Some 10,000 species are found only in freshwaters, a large proportion of which occurs in lakes and ponds. The freshwaters are therefore disproportionately rich in species of fishes on the basis of area when compared to oceans. That could be viewed as the result of the patchy nature of inland waters and the resulting high endemism of the biota. Fish live in almost every conceivable type of aquatic habitat. They exhibit enormous diversity in size, shape, and biology.

Other vertebrate species occur in freshwaters: a few mammals, several reptiles, and many birds and amphibians. There

Table 1 Species richness of the freshwater sediment biota for many habitat types

<i>Taxon</i>	<i>Number of species described</i>	<i>Probable number of species</i>	<i>Range of local species richness</i>
Bacteria	>10,000	Unknown	>1,000
Algae	14,000	>20,000	0–1000
Fungi	600	1,000–10,000	0–300
Protozoa	<10,000	10–20,000	20–800
Plants	1,000	Unknown	0–100
Invertebrates	70,000	>100,000	10–1,000
Aschelminthes	4,000	>10,000	5–500
Annelida	1,000	>1,500	2–50
Mollusca	4,000	5,000	0–50
Acarii	5,000	>7,500	0–100
Crustacea	8,000	>10,000	5–300
Insecta	45,000	>50,000	0–500
Others	1,400	>2,000	0–100

Numbers are rough estimates and derived from many sources.

Table 2 Number of fish species recorded from several lakes connected to rivers systems

<i>Lake</i>		<i>Latitude</i>	<i>Area</i>	<i>Number of fish</i>
Chad	Africa	13° N	10–20,000	137
Turkana	Africa	3° N	6,750	51
Chilwa	Africa	15° S	675	31
Ngami	Africa	20° S	150	48
George	Africa	0°	270	30
Huron	North America	44° N	59,600	99
Erie	North America	42° N	25,700	113
Michigan	North America	44° N	58,000	114
Superior	North America	47° N	82,400	67
Great Bear	North America	66° N	31,150	12
Great Slave	North America	61° N	27,200	26
Big Trout	North America	54° N	616	24
Chapala	Central America	20° N	1,080	14
Nicaragua	Central America	11° N	8,200	40
Maggiore	Europe	46° N	676	21
Windermere	Europe	54° N	15	9
Ladoga	Europe	61	18,400	48
Aral sea	Europe	45° N	64,500	17

See also Table 3 for ancient lakes.

is no quantitative evaluation of the number of vertebrates whose life cycles include lakes or ponds, but it is far from negligible (see Table 2).

Biological Diversity and Ecosystem Functioning

Energy and nutrients in an ecosystem are transferred through successive trophic levels. Photosynthesis provides the basic food for herbivorous animals, which are eaten by the carnivores. Therefore, knowledge of the role of individual species and their relationships in aquatic systems is critical to understand the functioning of the system as a whole. Limnologists pointed out several key issues to the study of the relationships between species diversity and lake functioning.

Food Webs

Food webs are diagrams depicting which species in a community interact in feeding and describing which kinds of organisms in a community eat which other kind. Food webs are thus caricatures of nature, but they give a picture of the processes at work in ecosystems. Connectivity food webs are describing pathways along which feeding interactions occur. These interactions change at least seasonally and not all interactions are equally strong. The interaction web emphasizes connections that appear to have a large effect on the dynamics of the food web structure and function. Food webs occupy a central position in community ecology. Many important interactions (e.g., competition, predation) cannot be isolated from a food web context because the outcome of these interactions can be modified directly and indirectly by other members of the web.

For a long time food webs served principally as heuristic devices, useful in depicting complex ecosystems as diagrams composed of many interactive parts and enhancing our understanding of pathways of energy and material transfer in aquatic ecosystems. However, the recent surge of interest in food webs seems related to the question of the functional role of biodiversity (discussed later).

Few if any of the aquatic food webs are unimpacted by humans both at a local and a global scale. For example, fisheries food webs are complex, involving multiple trophic levels at several spatial and temporal scales. Fish species offer a wide range of body sizes and feeding habits, and thus have a variety of food web roles and interactions with other species. Exploitation of fishes may result in major changes in food webs. However, the consequences of species removal through fisheries are an almost unexplored field of research in most freshwater systems.

The Top-Down Control

In the classical limnological approach, it was usual to consider freshwater ecosystems as operating in a physical-chemical milieu that, largely through nutrient availability, conditions the food chain from primary producers to top predators. In this “bottom-up” control, competition between primary producers for limiting nutrients determines the state of higher trophic levels. A reverse viewpoint, the “top-down control” slowly became prominent. It argues that the effects of top predators cascade down the trophic chain and are responsible for controlling the state of the entire ecosystem. The predators, near or at the top of the trophic pyramid, may be fishes but also may be birds, mammals, and so on, as well as invertebrates. Through grazing, for instance, fish have direct effects on the composition and abundance of phytoplankton, periphyton, and macrophytes, as well as on the dynamics of plankton and benthic communities. Size-selective predation by fish may not only play a major role in the population dynamics of prey species, but also result in shifts in the relative abundance of species.

Predation is now considered to be a major driving force in shaping zooplankton communities. A great number of papers emphasized the size-related alterations in zooplankton communities as a consequence of planktivorous fishes, which select the largest available prey and may rapidly reduce the density of large zooplankters, resulting in a shift of the prey community to small species, predominantly rotifers and small cladocerans. Extinction of large zooplankton has been documented in several habitats, usually following the introduction of new species of planktivorous fish.

Trophic cascades from fishes to water quality in lakes are among the clearest examples of feedbacks from population to ecosystem processes (Carpenter and Kitchell, 1993). A shift in the species composition and size distribution of the fish assemblages alters the community composition and size distribution of the herbivorous zooplankton. The impact of herbivory on phytoplankton depends on the relative abundance of certain herbivores with wide diets, high grazing rates, and rapid population growth rates. Population of these key-stone herbivores are sensitive to fish predation. In addition, the size distribution of fishes and zooplankton and their

migratory behavior largely determine the rate and spatial pattern of nutrient recycling in pelagic ecosystems. In whole-lake experiments, manipulations of fish community structure have caused significant changes in primary production, algal biomass, nutrient recycling, and sedimentation rates.

Relationships Between Biodiversity and Ecosystem Stability

A major concern for limnologists is to predict response to stress. For a long time, the so-called conventional wisdom in ecology was that increased complexity within a community leads to increased stability. Complexity is used here to mean more species, more interactions between them, and more pathways. The basic assumption is that if the number of pathways increases, any blockage at one point of the network would be compensated for by the opening of another pathway. However, until now this conventional wisdom has not received much support from field or experimental work. Therefore some basic questions remain open and are of particular concern for freshwater lakes:

- How is system stability and resistance affected by species diversity, and to what extent could the integrity and sustainability of ecosystems be maintained in spite of species deletions resulting from degradation of environmental conditions?
- Are rare species an insurance of ecosystem stability? Do these rare species play a role in ecosystem functioning? One hypothesis is that the most stable ecosystems in terms of key functions are those richest in species. However, well documented studies of rare species substituting for declining common species in the maintenance of key freshwater ecosystem functions following disturbance are scant.

Role of Intra- and Interspecies Communication Systems in Ecosystem Dynamics

The structure of the biota is determined by complex interactions between individual organisms acting at different trophic levels. It is now becoming clear that besides energy transfer from one trophic level to another, there is an exchange of information between trophic levels through infochemicals. Moreover, sexual pheromones, but also sounds, electric signals, and visual communication play a role in shaping the structure of the biotic community. This diverse communication network has biological consequences and may modify the behavior of aquatic animals, such as migrations. This is a fairly new field of research.

Biological Productivity and Biodiversity: The Case of Eutrophication

The biological structure and internal biological control mechanisms of freshwater lakes are highly affected by lake water nutrient level and by the extent of nutrient loading. Limnologists distinguish oligotrophic lakes, which are generally deep with steep slope and are characterized by low nutrient levels and clear water. The biomass at all trophic levels is small. On the opposite, eutrophic lakes are often shallow with

gradually sloping edges. The most characteristic features are high nutrients levels, the abundance of plankton, and low water clarity.

One concept of lake succession considers that lakes pass through different trophic states, beginning with low fertility or oligotrophy, gradually moving to a moderately productive or mesotrophic state to reach finally the eutrophic stage. This succession may happen in undisturbed lakes. However, eutrophication (sometimes called cultural eutrophication) is now widespread as a result of human activities. Eutrophication may be defined as the process of enrichment of a water body due to an increase in nutrient loading. The most important nutrients causing eutrophication are phosphates, nitrates, and ammonia. All these chemicals are abundant in waters released from sewage treatment works and from surface and groundwater runoffs in intensive agriculture areas.

The most obvious consequence of eutrophication is the increased aquatic plants and phytoplankton growth, an overall increase in biomass, and a shift in species composition of the lake. For example, at low P-concentrations, north European shallow freshwater lakes are usually in a clearwater stage; submerged macrophytes are abundant, potential piscivores are present in large numbers, and predation pressure on zooplankton is consequently low. At some higher P-concentrations, there is a shift to a turbid stage: submerged macrophytes disappear and the fish stock changes. The fish biomass rises and there is a shift from a system dominated by pike (*Esox lucius*) and perch (*Perca fluviatilis*) to one exclusively dominated by planktivorous-benthivorous fish, mainly bream (*Abramis brama*) and roach (*Rutilus rutilus*).

The Case of Ancient Lakes Species Flocks

About a dozen lakes in the world are up to three orders of magnitude older than most others (Table 3) (Martens, 1997). Such lakes have exceptionally high faunal diversity and levels of endemism.

An important characteristic of ancient lakes biodiversity is the existence of "species-flocks." An aggregate of several species should be identified as a flock only if its members are endemic to the geographically circumscribed area under consideration and are each others' closest living relatives. Briefly speaking, a species flock has to be monophyletic. At present, different rich species flocks for fish and invertebrates have been identified in various ancient lakes, which are therefore exceptional natural sites for the study of speciation patterns.

The processes accounting for these radiations are a matter of debate, but there is more and more evidence that sympatric speciation may occur in isolated water bodies. These species flocks are sometimes considered to be a world heritage that is endangered and has to be preserve from destruction by human activities (Coulter *et al.*, 1986; Nagelkerke *et al.*, 1995) (see Table 3).

Fish Species Flocks

The most striking feature of the Great East African Lakes (Victoria, Tanganyika, Malawi) is that each has its own highly endemic lacustrine Cichlid fauna. In Lake Victoria, according to our present knowledge, there is a cichlid species flock of more than 500 endemic haplochromine species. The true species number is almost certainly even higher (Seehausen, 1996). The age of this flock was estimated at 200,000 years, but it is most likely that Lake Victoria had entirely dried up as recently as 12,400 years ago, so that most of the endemic cichlid flock would have evolved during the past 12,400 years (Johnson *et al.*, 1996). In Lake Malawi, the diverse cichlid fauna of this lake could also total much more than 500 species. Species flocks are also reported for the clariid catfish *Dinotopterus* (10 species).

The Lake Tanganyika cichlids are slightly less diverse. However, morphological and electrophoretic data both suggest that several lineages of cichlids from Lake Tanganyika are much older than the Lakes Victoria and Malawi lineages and can be traced back to at least seven distinct ancestral lineages. Species flocks also occur in noncichlid families: seven Mastacembelid species, six species of the bagrid *Chrysichthys*, seven species of *Synodontis*, and four species of the Centropomid *Lates* (De Vos and Snoeks, 1994).

Rates of speciation in cichlids can be astonishingly fast. That has been known since the discovery of five endemic species of cichlids in Lake Nabugabo, a small lake less than 4000 years old and separated by a sandbar from lake Victoria. Still faster speciation rates were suggested by the finding that the southern end of Lake Malawi was dry only two centuries ago, while it is now inhabited by numerous endemic species and "color morphs" that are only found there and are believed to have originated during the past 200 years.

The remarkable diversity of the large barbs (genus *Barbus*) in Lake Tana (Ethiopia) constitutes a potential species flock that has been discovered recently. Nagelkerke *et al.* (1995) hypothesized that intralacustrine speciation has occurred among the barbs of Lake Tana and possibly is still going on.

Table 3 Summary of physical and biological characteristics of some of the larger extant ancient lakes

Lake	Age (My)	Max. depth. (m)	Area (km ²)	Number of animal species	Number of endemic	Number of fish species	Number of fish endemic
Baikal	35–30	1,700	31,500	1,825	982	56	27
Tanganyika	9–12	1,470	32,600	1,470	632	330	241
Malawi	4.5–8.6	785	30,800			> 600	> 600
Victoria	0.6?	70	70,000			> 500	> 500
Titicaca	3	284	8,448	533	61	29	23
Ohrid	2–3	295	348			17	2
Biwa	4	104	674	600	54	57	11

In South America, the native fish fauna of Lake Titicaca includes the genera *Trichomycterus* and *Orestias*, both endemic to the Andean Altiplano. Twenty-four *Orestias* species are presently recognized in Lake Titicaca (Lauzanne, 1992). However it is probably not a monophyletic group but rather an assemblage that includes, in part, several species flocks.

Lake Baikal (East Siberia) hosts a very diverse fauna, with some 2500 described species (most of which are endemic), which might constitute 50% of the total amount. At present, Lake Baikal comprises 56 species and subspecies of fish, which belong to 14 families (Sideleva, 1994), a group of six species and subspecies, belonging to three families (Thymallidae, Coregonidae, and Acipenseridae), which are relatively endemic; another group of nonendemic fauna includes 21 species and subspecies, which belong to Cyprinidae, Percidae, Cobitidae, Esocidae, Gadidae, Salmonidae, Siluridae, and Eleotridae.

In Asia, Lake Lanao was formed by a lava flow that dammed the streams flowing southwest. The cyprinid fauna presents a widely acknowledged example of adaptive radiation. Of the 23 cyprinid species presently known from Mindanao Island, 15 are reported from Lake Lanao (Kottelat and Whitten, 1996). Unfortunately overexploitation and exotic introductions have decimated the fauna, so that now only few endemic cyprinids are still present.

Lake Biwa is the largest and oldest lake in Japan. The deep basin as seen presently is supposed to have been formed 300,000 years ago. Most endemic fishes exist also since that time (Kawanabe, 1996). Some 500 plant and 600 animal species have been recorded. At present there are 71 species and subspecies of freshwater fishes found in Lake Biwa and its tributaries. There are 13 endemic species and subspecies of fish in Lake Biwa.

The only more or less pristine species flocks left in Asia are to be found in the lakes of the Malili River drainage of the Sulawesi Island (Celebes) in Indonesia (Kottelat & Whitten, 1996). Malili lakes (Lakes Towuti, Matano, Mahalona, Wawontoa, and Masapi) constitute a system of lakes partially isolated from each other and completely isolated from other freshwaters. As a result, most of the animal species known from the lakes are endemic.

Invertebrates

Mollusks focus our attention on parts of the world that seem to be hot spots of endemism, where the resident clades are remarkably more diverse than in other similar environments. Long-lived lakes are prime examples of these evolutionary theaters. Particular clades, such as the hydrobioid and ceratioidean prosobranchs and the planorbid pulmonates, show repeated patterns of diversification in both extant and fossil long-lived lakes, revealing the common patterns that make them prone to speciate (Michel, 1994). The process of diversification is tied to intrinsic characters shared by many of these clades: reproductive and dispersal strategies (brooders and poor dispersers), genetic structure (tightly constrained genetic systems), morphology (often relatively thick and ornamented shells), substrate specificity (hard bottom stenotopy), and physiology (depth tolerance). The most notable examples of these evolutionary theaters are extant

Table 4 Endemism in ancient mollusk fauna (ancient lakes and rivers)

Lakes	Baikal	Ohrid	Tangan.	Titicaca	Biwa
Mussels	2	1	12	0	
% end.	0	0	75		
Sphaeriidae	10	9	3	4	
% end.	30	22			
Prosobranchs	72	47	52	16	11
% end.	93	91	84	93	72
Pulmonates	61	25	16	3	16
% end.	77	48	6	33	62
Total species	145	82	81	19	27

lakes Tanganyika, Baikal, Ohrid, Titicaca, and fossil lakes Idaho, Biwa, and Turkana. However, examples of gastropod radiations are also found in river systems (see Table 4).

Among Crustacea, gammarids have also undergone an enormous evolutionary radiation in Lake Baikal, with a total of 259 species, 98% of which are endemic. There are also several species flocks of Ostracods reported from ancient lakes (Martens *et al.*, 1994).

Major Threats to Biodiversity in Lakes

The concentration of people around freshwater systems has resulted in a much greater degree of degradation to these systems than most open marine or even terrestrial systems.

Competition for Water

Competition for water may result in the total or partial desiccation of lakes and ponds through various diversions and impoundment of tributaries. Water is withdrawn most often from aquatic systems for irrigation, flood control, and urban and industrial consumption. A spectacular example is provided with the Aral Sea, a large saline lake in the terminus of an extensive inland drainage basin in south-central Asia. Water diversion for irrigation purposes of most of the waters in inflowing rivers of the Aral sea, as well as poor agricultural practices, resulted in a marked fall of water level (c. 15 m) and an increase in salinity (from c. 10 to 30 g/l) since the 1960s. These changes have resulted in the degradation of the natural environment. Fish have virtually disappeared from the lake and the diversity of associated bird and wildlife communities has decreased. Many invertebrates also disappeared (Williams and Aladin, 1991).

Habitat Alteration

Siltation from erosion of the lake basin has direct adverse effects on fish by covering spawning sites, destroying benthic food sources, and reducing water clarity to visual feeding animals. However, the increased turbidity may also have indirect effects on biodiversity in lakes. Seehausen *et al.* (1997) provided evidence that increasing turbidity (as the consequence of deforestation and agricultural practices) by curbing the impact of sexual selection on sexual isolation is responsible for the

decline in cichlid diversity in Lake Victoria. Actually, mate choice in these cichlids is determined on the basis of coloration, and strong assortive mating can quickly lead to sexual isolation of color morphs, which is increasing and probably started in the 1920s. By constraining color vision, turbidity interferes with mate choice (Seehausen *et al.*, 1997). The reduced effectiveness of signals causes relaxation of sexual selection for color, with consequent loss of male nuptial coloration and erosion of species diversity due to a breakdown of reproductive barriers. Dull fish coloration, few color morphs, and low species diversity are found in areas that have become turbid as a result of recent eutrophication. This is proof that human activities that increase turbidity destroy the mechanism of diversification and the maintenance of diversity.

Species Introductions

The introduction of alien fish into inland waters has occurred all around the world. The main goals of deliberate introductions by fishery officers were initially to improve sport fisheries and aquaculture, or to develop biological control of aquatic diseases, insects, and plants, or else to fill supposed "vacant niches" and improve wild stocks in old or newly created impoundments.

The introduction of alien species has been considered as the main causes of extinction of endemic species flocks in several ancient lakes. In Lake Lanao, the introduction of the white goby (*Glossogobius giurus*) in the early 1960s resulted in the elimination of numerous species of endemic cyprinid fish. In Lake Titicaca the rainbow trout *Salmo gairdneri* was accused of seriously threatening the endemic *Orestias* fauna and for having been responsible for the disappearance of species such as *Orestias cuvieri*. In Lake Biwa, the recent increases in numbers of the exotic bluegill *Lepomis macrochirus*, black-bass *Micropterus salmoides*, and *Channa maculata*, have been mirrored by serious declines in the native species *Onchorhynchus rhodurus rhodurus* (an endemic), *Hemigrammocypripis rasborella*, and *Hymenophysa curta*.

Much has been said about the impact of the introduction of the Nile perch on the hundreds of endemic haplochromines of Lake Victoria (Lévêque, 1997). In the early 1980s this impact was considered an ecological and conservation disaster (Coulter *et al.*, 1986). However, it was later recognized that predation by *Lates* may not be solely responsible for the depletion of haplochromine stocks, and that the haplochromine stock was already affected by fisheries before the establishment of *Lates*, particularly by unregulated fishing or by trawling techniques introduced in the Tanzanian part of the lake. Lake Victoria is now invaded by water hyacinth, and the remaining fish fauna is therefore more and more threatened.

Transport through ballast water is probably one of the most important pathways for alien species invasions in several places, including the North American Great Lakes (Mills *et al.*, 1993). That is the case for the zebra mussel introduced into the Great Lakes, apparently in 1985 or 1986, which spread dramatically throughout the waterways of both Canada and United States, expansion with serious economical and ecological consequences. The recent finding of

individual mitten crabs (*Eriocheir sinensis*), a European flounder (*Platichthys flesus*), and the establishment of the alien gastropod *Potamopyrgus antipodarum* in Lake Ontario in 1995 demonstrate that the process of invasion is still going on at a fast rate.

One of the major problems in freshwater species introductions is their irreversibility, at least on the scale of a human's lifetime. Once introduced and established, it is impossible, given current technology, to eradicate a fish, a mollusk, or a plant species from a large natural water body. As a consequence, we are likely to see a continued reduction in native aquatic biodiversity and an increased homogenization of the world's freshwater biotas.

Fisheries Practices

One of the major threats to the unique species flocks of ancient lakes are the fishing practices and particularly overfishing and introduction of new fishing practices. According to Coulter *et al.* (1986), the collective experience in recent years on the African Great Lakes seems to show that large-scale mechanized fishing is incompatible with the continued existence of the highly diverse cichlid communities. Cichlids appear especially vulnerable to unselective fishing because of their particular reproductive characteristics. The structure of endemic cichlid fish communities in the African Great Lakes can change dramatically within a few years when trawlers and other such fishing gear are used. Actually, a number of authors have recorded the effects of over-fishing in Lake Victoria, from the decline of some species to the virtual disappearance of others, and the history of the fishery was briefly reviewed by Witte *et al.* (1992).

It has also been suggested that parks should be developed (Coulter *et al.*, 1986) and that fishing should be rendered impossible in certain areas by placing obstructions on the bottom that would snarl trawls. Lake Malawi National Park will very probably afford protection to widespread species, but no data are at present available to confirm this hypothesis. It is unknown yet whether these reserves can adequately preserve the integrity of populations, but that is probably only possible for stenotopic populations whose distribution coincides with the park area. The size of the reserves, the intensity of fishing in nearby areas, and the possible influence of pollution or introduced alien species should also be taken into account.

Pollution

Pollution can affect aquatic biota through direct mortality at any life stage or by sublethal effects influencing predation, foraging, and reproduction. The eutrophication of Lake Victoria during the past 25 years is quite well documented. Enhanced quantities of nutrients appear to have been entering this lake for many years, both through rivers and from aerosols as a result of human activities in its watersheds. The eutrophication could lead to increased oxygen demand in the lake's deep water and thus decrease the hypolimnetic volume habitable by fish during seasonal stratification. This phenomenon is partly responsible for the threatening or

disappearance of cichlid species belonging to the haplochromine flock.

The release of sulfur and nitrous oxides from the burning of fossil fuels may be transported great distances before being transformed chemically into sulfuric and nitric acids and deposited as rain, snow, or dust. When acid rains occur over areas where waters are poorly buffered, the chemistry and biology of freshwaters can be changed dramatically. Many softwater lakes have been acidified both in North America and Europe, but evidence has accumulated for its occurrence in China, the former Soviet Union, and South America. Monitoring studies indicate a general impoverishment of species numbers in lakes as they become more acidic. Many lakes in the northeastern United States have lost 30% or more of the species in some taxonomic groups. In many northern European countries, acidification strongly modified the fish composition and abundance in lakes.

Glossary

Climax The stable ecosystem that is supposed to result from a sufficiently long period of unchanging environment.

Clone A group of individuals formed by vegetative reproduction from a parent. This term applies particularly to those trees and plants that reproduce by creeping stems or by suckers from roots, forming circular patches of genetically identical individuals.

Coppice Regrowth of a felled tree from the stump.

Cultural ecosystem Ecosystem produced by the long-term interaction of wild plants and animals with human activities.

Endemic Plant or animal species limited to a small area of the world, for example, one island or mountain range.

Heath Open vegetation dominated by dwarf undershrubs usually of the family Ericaceae.

Meadow Grassland maintained by mowing.

Moor Open vegetation, dominated especially by dwarf Ericaceae and *Sphagnum* mosses, on peaty soil.

Pasture Grassland maintained by grazing domestic animals.

Pollard A tree repeatedly cut at about 6–10 ft above ground to produce successive crops of wood.

Savanna Grassland (or other nonforest vegetation) with scattered trees.

Seminatural Vegetation that owes its character to human activity, but in which the plants are wild, not sown or planted. Examples: coppice woods; most heathland; some savannas.

Wildwood Wholly natural forest not affected by sedentary human activities such as agriculture and pasturage, widespread in prehistoric times (including earlier interglacial periods) and still surviving in remote places.

Woodland Forest forming part of a cultural landscape.

Wood-pasture Cultural ecosystems, often savanna-like, combining trees and domestic animals.

Introduction

Human intervention often does not efface all signs of previous ecosystems. The traveler in Texas, despite 170 years of often intense activity by settlers, has no difficulty in recognizing the presettlement vegetation regions (Pineywoods, Blackland Prairie, Post Oak Savanna, etc.).

Even in Britain, after 6000 years of settlement, the landscape is still not wholly artificial. By careful search, one still finds remains of the mid-Holocene vegetation categories (limewoods in lowland England, oakwoods in the north and west, pinewoods in east Scotland). Superimposed on these are the largely artificial ecosystems of arable farmland, sown grassland, and forestry plantations; the seminatural ecosystems produced by the responses of wild plants and animals to continuing land-use (old pasture, hedges, moorland) or to past land-use (abandoned mines, derelict forestry plantations); and the wealth of biodiversity contained in cities, old pits, and industrially derelict land.

Cultural ecosystems are often contrasted with wildwood or “virgin forest,” the aboriginal vegetation of much of the world’s land surface before the impact of settled human cultures. Wildwood itself, however, may already have been altered by the activities of nonsettled peoples. There is abundant evidence to show that hunting and gathering were not simple, unorganized activities, but could have profound effects on landscape and ecology, even in places remote from the activities themselves. A probable example is the extermination

of elephants and other great mammals by Paleolithic peoples. The loss of the only animals capable of breaking down big trees could hardly fail to have profound, if as yet little known, consequences. From the early Holocene, if not earlier, land management by burning affected the ecology where vegetation was combustible, especially in Australia and North America. These activities, as far as we know, created only simple land-use patterns: they would alter, for example, the boundaries between forest and prairie or between combustible and non-combustible vegetation. Some of the Texas ecosystems, such as the Edwards Plateau savannas, were probably produced by Native American land-use and taken over by settlers. The introduction of settlements, domestic animals, and cultivated plants – in European terms, the coming of Neolithic cultures within the past 8000 years – began to create the diversity and complexity of land-use patterns that is familiar today.

Human Activities and Climatic Change

It used to be thought that, given enough time, the plant and animal communities in an area would settle down to a stable *climax* state, determined only by the climate and (maybe) geology and changing only slowly in response to evolution. This may have been so in the Tertiary geological period, but in the Quaternary the dominant factor has been climatic change. Glacial cycles in high latitudes destroyed all vegetation over large areas, including much of Britain. In middle latitudes and

even in the tropics, although there has been little ice cover, climatic changes such as drought have been sufficient to displace or destroy most of the interglacial plant communities.

There have been many glacial cycles over the past 2 million years. In much of the world, forest has been the “normal” vegetation only in interglacial periods like the present, of at most a few tens of thousands of years each. Changes of climate have been too rapid for plants and animals, apart from annuals and other fast-reproducing species, to keep up with them by evolutionary change.

Human activity has recently become the predominant force shaping the world’s ecosystems. However, it did not burst into a world of stable environment in which evolution had previously been the predominant force. It came on top of a period of unusual instability: climatic change had been operating on a time scale not much longer than that of human activity itself. In Britain humanized ecosystems have existed for about 6000 years; the “virgin forest” preceding them had existed for at most another 6000 years and was itself affected by the activities of Mesolithic and Paleolithic people.

Climatic change and human activity overlap in time, and their effects can be difficult to separate. In the Mediterranean, the present, rather arid, ecosystems are variously attributed to the strongly seasonal climate with its hot dry summers and to the activities of people “degrading” what would otherwise be a more forested landscape. In reality, the present climate is only about 6000 years old and set in at the same time that prehistoric people were having a profound effect on the landscape.

Properties of Crops and Domestic Animals

Land-use patterns depend on the ecological behavior of a few species of major crop plants and domestic animals, which are usually not indigenous to the region.

Most of the crop plants of European-style agriculture originated in the steppes of southwest and central Asia and have a particular set of ecological requirements. They have modest moisture needs, rather high needs for mineral nutrients, and are very intolerant of waterlogging and shade. As they spread, first to Europe and later to European colonies, farmers strove to convert more and more of the world’s ecosystems to an imitation of a Turkish steppe in which wheat and barley are at home. Of the multitude of indigenous American crop plants, only a few – corn, potato, and tobacco – have been widely grown in Europe; these are the few whose ecological requirements are not too different from those of Southwest Asian crops, although they need more moisture. Rice is a Southeast Asian crop with very different requirements, growing in wetlands and making possible the great wetland civilizations of Asia. Hence it comes about that generations of farmers have sought to destroy Europe’s fens and convert them into artificial steppe, whereas Southeast Asian farmers, with the utmost ingenuity, have contrived to turn hillsides into artificial fen (Figure 1).

Many tropical crops, however, will grow in moderate shade, and some require it. The distinction between forest and farmland, which is so sharp in most European-style agriculture, is not always clear in the tropics.

Figure 1 Cultural landscape of terraced rice fields, carefully leveled so as to be irrigated. Land of the Hani people, Yunnan, SW China.

Keeping domestic animals also involves destroying or modifying natural ecosystems. Cattle, sheep, and goats eat tree leaves but are not forest animals. If kept in the shade of trees, they soon eat all the leafage within reach, creating a *browse-line* beneath which nothing is allowed to grow. To keep them in manageable numbers requires at least some gaps between the trees, in which grasses and low herbage will grow. Pigs, although often thought of as acorn feeders, cannot be kept in forest alone. Acorns are available for only a few months of the year and contain insufficient protein to sustain pigs by themselves. The world’s cultural ecosystems would be very different had monkeys been domesticated for human food.

Fields, Hedges, and Terraces

In some parts of the world, arable fields are impermanent, being created out of forest or grassland, cultivated for a few years, and then allowed to revert to natural vegetation. The landscape consists of a mosaic of areas in different stages of reversion. This *shifting cultivation* is typical of regions too infertile to support even primitive agriculture permanently, especially in the tropics. In more fertile regions, such as most of Europe, people avoid having to repeat the immense labor of creating new farmland. Fields are permanent and tend to be private property with fixed boundaries.

In regions not yet reached by weedkillers, arable fields are seminatural ecosystems. Many weeds came from the original homelands of the crops they accompanied, and some annuals have evolved in parallel with particular crops: for example, cow-wheat (*Melampyrum arvense*), whose seeds resemble a grain of wheat, so that they are sown along with the wheat crop. In Japan, rice fields are complex aquatic ecosystems involving cyanophytes, water ferns, amphibians, and insects; some of the plants fix nitrogen and so benefit the rice crop.

Fields tend to be discontinuous. As well as boundaries where they adjoin forest, pasture, or roads, they have boundaries separating ownerships or subdivisions within an ownership (Figure 2). These are determined both by practicalities (e.g., erosion control) and by anthropological factors, such as land

Figure 2 Anglo-Welsh cultural landscape of small irregular fields, thick hedges, many hedgerow trees, and scattered farmsteads, of unknown origin but likely to be well over 500 years old. *Llanveynoe, Herefordshire, England.*

Figure 3 Ancient hedge between two fields, managed by coppicing. It has been cut down (leaving a few trees standing) and is beginning to sprout. In 2 years it will be back to its normal state. *Polstead, Suffolk, England.*

tenure, inheritance, or collectivization. The boundaries (hedges, banks, walls, etc.) provide a network of relatively natural ecosystems permeating the farmland. The size of fields varies from country to country. In parts of Canada or Australia, 100 acres is a small field. In Texas, the nineteenth-century allotments of 1 square mile (640 acres) are by now divided into at least 30 compartments in several ownerships. In the hedged parts of medieval England, a typical field would be of about 4 acres. In Crete, fields tend to be of about 1 acre. In Japan, with rice as an immensely high-yielding crop, even this would be a big field.

A *hedge* (in North America, a *fence-row*) is a row or strip of trees or shrubs forming the boundary of a field. In Europe,

these are often maintained by cutting in particular styles to form a barrier to keep cattle or sheep from straying into the next field; often trees are left at intervals either uncut or pollarded (**Figure 3**). In America, they are less managed.

In America and to some extent Europe, most hedges have arisen spontaneously as trees have taken root from wind- or bird-dispersed seed at the bases of fences or on balks or walls between fields. In England, hedges are thought of as deliberately planted, but can arise naturally, as many of the older hedges probably did. In Australia, hedges are rare, evidently because most eucalyptuses and other native trees have poor powers of seed dispersal.

Figure 4 Cretan cultural landscape in a semiarid climate. In the bottom of the basin are houses grouped into hamlets, with gardens, orchards, and small fields demarcated by dry-stone walls. Extending up the mountains are remains of terraces, on which grain used to be grown. *Asphéndou, Sphakiá, Crete.*

Hedges presumably go back in some countries to the beginnings of agriculture. In Europe, the earliest evidence for them is about 2000 years old; they probably go back much further, but leave little archeological record. In England, they are well documented for about 1200 years. Many individual hedges are at least 500 years old; these tend to be mixed in their composition, unlike the monotonous hedges of more recent origin.

Hedges are often thought of as linear wood-lots. This is partly true: in England, many hedges were periodically felled as if they were woodland, yielding crops of fuel wood and timber. However, in England and (from what the author has seen of them in America), hedges are distinct vegetation types in themselves, seldom corresponding in detail to the local forest. They usually lack the more exacting woodland plants, apart from those few hedges that are the surviving edges of grubbed-out wood-lots.

Hedges are important as diversifying what might otherwise be featureless farmland. They introduce tree-living (though not forest) birds to open country that would lack nesting sites. They are often regarded as corridors for movement of mammals across farmland.

In many mountainous and densely populated parts of the world, slopes are shaped into terraces to create flattish surfaces on which to grow crops (**Figure 4**). Banks or walls between terraces, like hedges between fields, can be significant sites for seminatural vegetation.

Forest and Woodland

It is often supposed that wildwood consisted of trees, trees, and nothing but trees, and only shade-bearing ground vegetation; gaps arising through the death of trees would promptly be filled by the growth of new trees. Examples can be seen where the dominant trees are of shade-bearing kinds such as

Abies and *Fagus* species. The argument that wildwood was like this is often based on the general doctrine of climax vegetation, rather than on evidence of the history of specific forests. Pollen analysis can exaggerate the dominance of trees, many of which produce more pollen than herbaceous plants. If this is allowed for, some wildwoods were much more diverse.

Frans Vera has advanced the theory that wildwood was a mosaic of areas of trees and areas of grassland, continually shifting under the influence of deer, wild oxen, and wild horses. Whether this was so is still controversial. It would explain why agricultural technology should have spread into the seemingly hostile environment of north-west Europe, where (in the continuous-forest theory) people would have had to expend immense labor on digging up trees to make fields before they could grow anything. It also explains why wood-pasture is such an important habitat.

In some tropical forests, there is vast biodiversity, owing to the many species of tree and the abundance of vines, epiphytes, and termites, which enable the trees themselves to support complex ecosystems. In other parts of the world, continuous forests, especially of densely shading trees, are relatively poor habitats: many of their plants and animals are concentrated in gaps, cliffs, watercourses, burnt areas, and other breaks in the continuous shade.

Ancient peoples destroyed some areas of forest to create farmland, grassland, and heath; they also affected the remaining forest by various forms of land management. Continuous forest is not very productive for most human purposes. Edible animals and plants occur sparsely, if at all, and the animals are difficult to catch. Tree fruits are out of reach in the high canopy.

Forests were not generally destroyed by people cutting down the trees in order to use them. The author knows of no instance in European history of a forest being destroyed – converted to

Figure 5 A coppice wood. The foreground has just been felled, leaving the stools from which new growth will arise. In the middle is an area of 2 years' growth since last felling. An older part of the wood forms the background. *Bradfield Woods, Suffolk, England.*

nonforest – solely by people using up the trees. Normally they would cut the trees suitable for the purpose in hand and leave the other trees. The result would be a depleted forest, unsuitable for that purpose until a new generation of trees had grown. This is not to be confused with a destroyed forest.

Great trees do not easily furnish wood for fuel and timber for construction. A big tree, when cut down, is a very intractable object. Until the coming of sawmills, vehicles, and railroads capable of dealing with giant trees, people preferred to use the smallest log that would serve the purpose and to manage forests to produce a succession of trees small enough to handle.

Coppicing is an important factor. Most European and North American trees, other than conifers, survive being cut down and sprout from the stump. Clonal trees, like European elms and American beech, sucker from the roots. Coppicing is one of the world's most important practices in historic forest management. By cutting down woodland every 5–30 years and allowing it to grow again from the stumps, a permanent succession of small stems can be assured, of sizes that are easily handled and suitable for light construction and fuel. It was often the practice to leave a scatter of trees of selected species to grow on for three or four cycles to yield constructional timber (Figure 5).

Coppicing has been the nearly universal woodland management in Britain, well documented for the past thousand years and known on archeological evidence for some 6000 years. It is the basis of historic forest management in many parts of the broad-leaved and Mediterranean zones of Europe and also in Japan. It was apparently not much practiced by Native Americans but was widely introduced by European settlers in America, where there are large areas of ex-coppiced wood-lots.

Coppicing affects biodiversity by drastically reducing the shade at the start of each cycle of felling and regrowth. Two or three years of relatively open conditions follow, ending as the

new growth closes in. This favors various woodland plants and animals. Low-growing herbs such as species of *Viola* and *Primula* flower in abundance in the years of extra light (Figure 6). Others such as *Euphorbia* species appear from buried seed produced by their parents at the last felling. Many insects feed on the leaves or nectar of these plants. The middle stages of regrowth, when there is a thicket of young stems, favor warblers and similar small birds – a famous English example is the nightingale (*Luscinia megarhynchos*). The dormouse (*Muscardinus avellanarius*), an English woodland mammal, favors the later stages.

Coppicing is often thought to be artificial, but the ability to coppice is widespread among the world's trees and presumably was an adaptation to some process in wildwood. Sometimes it is a response to fire, but it is not correlated with flammability: few pines (among the world's most flammable trees) will coppice, but fireproof trees such as elms and poplars coppice or sucker. American, European, and Japanese species of *Tilia* (lime, basswood) are self-coppicing and grow naturally in a multitemmed form; so do American and Japanese species of *Magnolia*. Possibly coppicing behavior is an adaptation to tree-breaking mammals: the axes of woodcutters are a replacement of the missing elephants, etc. The author has observed something like a coppicing ecosystem developed in eucalyptus forests in New South Wales after only the third or fourth successive logging (Figure 7).

Another historic woodland practice is the creation of permanent edges and open areas. In England, wood-lots have permanent edges (many of them are over a thousand years old) defined by banks and ditches, constructed as a conservation measure (Figure 8). They may also have permanent tracks and other open areas in the interior. In a typical wood-lot, well over half the plant species are associated with the boundary, with recently felled areas, or with permanent openings. The species of permanent openings tend to constitute plant communities of their own, distinct from those of

Figure 6 Oxlip (*Primula elatior*) flowering in abundance among hazel (*Corylus*) shoots of 1 year's growth since coppicing. Hayley Wood, Cambridgeshire, England.

Figure 7 Eucalyptus forest 2 years after being logged for the third or fourth time. Note the abundant regrowth and ground vegetation. Merimbula State Forest, New South Wales.

temporary clearings and of grassland away from woodland. On pollen evidence, something like these permanent open areas already existed in wildwood.

Wood-Pasture and Savanna

Where the environment becomes too dry or cold for forest or where there is too much grazing, forest changes into nonforest in various ways. The trees may suddenly stop, or there may be a zone of trees reduced to the stature of shrubs, or a mosaic of patches of forest and patches of nonforest. Alternatively, there

may be a zone, often of great extent, of scattered trees among grassland. This constitutes tropical and subtropical savanna ecosystems and their extensions into northern latitudes. The trees may be single, as in the wood-pasture ecosystems of England, the *dehesa* landscapes of southwestern Spain, and the eucalyptus savannas of Australia. Or they may be in groups, as with the oak and elm *motts* of middle Texas (**Figure 9**). This depends on the properties of the trees: Texan *Quercus fusiformis* and *Ulmus crassifolia* are clonal trees that sucker.

It used to be thought that the "natural" savannas of Africa and Australia were very distinct from the semiartificial treed grasslands and treed heaths of Europe, which were regarded as

Figure 8 Edge of an English wood. The bank with external ditch was constructed about 1000 years ago by the monks of Bury St. Edmunds Abbey to demarcate their wood-lot. The trees on the bank have just been cut; in the interior, they are of 1 year's growth. *Bradfield Woods, Suffolk, England.*

Figure 9 Savanna in middle Texas. The prairie (rich in spring and summer flowers) is dotted with motts – clonal patches – of Texas live oak and Texas elm. This is a cultural landscape of Native American origin, which was already in place when the area was settled in 1846. It needs to be maintained by grazing or burning, without which it is invaded by juniper (*Juniperus ashei*) and turns into forest. *Valley Mills, Texas.*

“degraded forest,” meaning forest from which some trees had been removed. Recent research makes the distinction less clear: many tropical savannas are at least partly the result of ancient land management, especially by burning. The pollen record of European wildwood, moreover, often contains nonshade-bearing undershrubs and herbs, showing that it must have had open areas as well as trees.

Cultural treed grasslands are usually differentiated from forest by there being enough browsing animals to prevent trees from occupying all the space. The amount of browsing needed to do this varies. Where the climate is so dry or cold as to be marginal for tree growth, it takes less browsing than in regions, such as England, well within the climatic limit of forest. (In some hotclimate savannas, conversely, the grasses

Figure 10 A complex medieval wood-pasture, combining old grassland, ancient pollard trees, and coppice wood-lots: a particularly important juxtaposition of habitats, reproducing some characteristics of wildwood. *Hatfield Forest, Essex, England.*

are the dominant partners, and too much browsing encourages trees.)

The limits of “natural” treed grassland are vague and controversial. The amount of browsing – the numbers and behavior of the animals – is the most difficult aspect of prehistoric ecosystems to ascertain. Trees tend to be exaggerated, because many nontree plants produce sparse or non-diagnostic pollen grains and also because pollen analysts are trained to interpret tree pollen in terms of forest rather than of single trees.

In glacial times, parts of Europe not covered by ice were evidently dry as well as cold. The natural vegetation consisted of either patches or scatters of trees, which pollen analysts call “forest steppe.” This was the situation for at least four-fifths of the past 2 million years, punctuated by interglacials when large areas of forest became possible. In the present interglacial, when the climate became favorable for trees, non-shade-bearing plants became very local – except in the drier parts of southern Europe, where forest was still patchy and savanna-like.

When people took to keeping cattle, sheep, and goats, they replaced an unknown, but probably sparse, scatter of wild herbivores by local concentrations of domestic animals. To feed them, they turned forest into grassland; but they also kept domestic animals in the remaining forest. This involved managing the forest in a different way from where wood was the product. The trees would have to be sparse enough for pasture to grow between them on which the livestock might feed. Trees were also cropped, not by coppicing – for the animals would eat the young shoots and kill the stools – but by the practices of pollarding and shredding, cutting the tree high enough for the shoots to arise out of reach. Sometimes wood was the objective, but in climates where grass did not grow all year, it was the practice to harvest leafy tree branches to store instead of hay for feeding the animals in the cold of winter or drought of summer.

Such seminatural wood-pasture ecosystems came to occupy large areas of Europe and Asia, often associated with communal land management. In England, there was a further development with deer as semidomestic livestock from the eleventh century AD onward. Landowners would keep deer (native and introduced) for meat and as a status symbol in enclosed parks. The king, moreover, had the right to keep deer on certain commonlands, such as Epping Forest and the New Forest, and to kill and eat them. Parks and Forests often contained treed grassland on which deer and other livestock fed. There could also be elaborate systems of temporary enclosure to combine livestock with coppice woods.

Wood-pasture is a most important ecosystem, especially for insects and birds that require both trees (for example as nest sites) and grassland (Figure 10). The inland bird fauna of England as a whole falls into this category. Wood-pasture also can preserve ancient trees. A large proportion of the fauna and flora of trees, especially beetles and lichens, is associated with the specific habitats of old trees: old dry bark, heartwood rotted by particular fungi, and cavities of various sizes. These are specialized, poorly dispersed animals and plants and presumably existed in wildwood. Forest trees are not an ideal habitat, for the lives of old trees are often shortened by the competition of neighboring trees. Coppice woods and managed forests are inhospitable to them, unless the ancient bases of coppice stools are a suitable habitat. However, wood-pasture is often very good for old trees and the organisms that live on them. The trees are free from competition and can live to a great age, especially as pollarding prolongs the lives of many species. Much of the information so far comes from England, where the New Forest, Windsor Forest, and Sherwood Forest are major sites for the invertebrates of ancient trees.

Wood-pasture is now much reduced in northern latitudes, but the author has found traces of it as far north as Sweden.

The area surviving in England, though small, contains some supremely complex and important examples. It still flourishes in southern Europe, covering about one-sixth of Portugal and one-eighth of Spain, although few of these contain ancient trees. It extends eastward into the Himalayas. At one time, it was evidently extensive in Japan, where old pollard trees can still be found embedded in forests. In North America, Native Americans and settlers both operated savanna-like landscapes, but pollarding was rare. In Australia, savannas are widespread and sometimes contain trees dating from presettlement times, but often the grassland component has been displaced by introduced grasses and herbs.

Wood-pasture is an important ecosystem for biodiversity: it perpetuates a different set of plants and animals from coppice woods. The most significant examples remaining are those few in which ancient trees and seminatural grassland are both preserved.

Grassland

Many of the world's grasslands are regarded as natural prairies, in regions too dry, or too cold, or too much grazed for trees. Others are part of a cultural landscape in regions that would naturally be forested; if not grazed, they revert to forest. There are large intermediate areas where natural grassland has been extended by burning and other forms of land management.

Much grassland in Europe, America, and Australia is sown pasture, little different from other arable crops. This practice goes back only three centuries. Previously, grassland was permanent, managed as either pasture (grazed) or meadow (mown for hay). Pasturage often goes with communal land use, as in the American Wild West or the chalk downlands of England.

Seminatural pasture grassland in England goes back to the Neolithic period, when the forests that covered the chalklands were converted into open land; prehistoric monuments such as Stonehenge were meant to be visible from a distance. Often there was a phase of farmland before the historic grasslands were established.

Meadow is a more productive kind of grassland, yielding hay which is dried and stored to feed animals in winter when the grass is not growing. This requires iron tools with which to cut the grass. As a large-scale land use, meadow is mainly of the past 1500 years. It was located especially in floodplains, which in medieval England were the most valuable land. In the sixteenth century, elaborate irrigation systems were developed to advance the growth of meadow in spring. Grasslands were often part of a highly integrated pattern of land-uses that transferred nutrients, via the dung of cattle and sheep, to plowland and meadow.

A contrasting type of hay meadow is that on mountains, for example, in northern England or in the Alps. In Italy, in the northern Apennines, the grasslands, originating in the Iron Age, were maintained for centuries to feed local livestock and those of the city of Genoa; recently, they have largely turned into forest and their distinctive plant communities have been lost.

Old grasslands are the classic "seminatural" vegetation. They are artificial in that they were created by human activity,

and disappear if that activity is withdrawn. They are natural in that nobody sowed the grasses and other plants of which they are composed. They are of many kinds, depending on whether they were pasture or meadow, on the geology, and on which animals fed on them. Chalk pasture is a dry, relatively infertile form of grassland that is one of the richest plant communities (in terms of plant species per square meter) in Britain. When grazed by sheep or rabbits, it is particularly rich in dwarf herbs and small undershrubs. At the other extreme, wet meadow is rich in tall grasses, sedges, and orchids.

Heathland

Heathland in northwestern Europe is open vegetation other than grassland, dominated by dwarf undershrubs especially of the family Ericaceae. It can be a very rich plant community, with many herbs and also characteristic butterflies and birds. It is a seminatural ecosystem, maintained by grazing and cutting; without these, it quickly turns into woodland (Figure 11).

Heathland began in a small way in the Mesolithic period, about 10,000 years ago; people may have encouraged it as part of land management in favor of deer. It expanded in later prehistory, especially as browsing by domestic livestock encroached on forest. Throughout the historic period, it was extensive in England, especially on acid soils in low-rainfall areas.

Heathland should perhaps be seen as a northward extension of the undershrubby plant communities of the Mediterranean, known as *garrigue* and *phrygana*. These, too, are often thought of as the result of destruction of forest: on palynological evidence, they were relatively local and specialized ecosystems until the Neolithic period. However, they are more stable than heath, occurring in places too dry for tree growth. Often they fail to turn into forest if grazing is removed. Phrygana is one of the richest ecosystems in endemic plants.

The heaths of northwestern Europe have fared very badly in the past 200 years. Little remains outside Britain, and even there, heaths, where not made into arable fields or forestry plantations, have been allowed to turn into woodland.

Moorland

Moorland, although often confused with heath, is really a southward extension of the peaty tundra of the Arctic. It is characteristic of northwestern Europe, especially mountains (Figure 12); it still covers half of Scotland.

Moorland is dominated usually by ericaceous undershrubs, especially heather, *Calluna vulgaris*. Unlike heath, it occurs in high-rainfall areas and has a peaty substratum. It grades into blanket bog, with pools and abundant *Sphagnum*.

Moorland is more stable than heath and less obviously a cultural ecosystem. It gradually extended during the Holocene, covering areas that once had forest. Sometimes there was an intermediate stage of pasture or even arable land: on the plateau of Dartmoor, southwest England, the boundaries of Bronze Age fields can still be traced. However, it is not clear

Figure 11 Heathland, several hundred years old, now insufficiently grazed: if trees are allowed to take it over, they will destroy its value as a habitat. *Holt, Norfolk, England.*

Figure 12 Medieval landscape on the border of Wales, with hedged fields and farmsteads in the valley and moorland on the thin soils of the plateau and on screes below the cliffs. *Cwm Olchon, Herefordshire, England.*

how far the spread of moorland was due to the lapse of time and accumulation of peat, to a change to a wetter climate encouraging peat to grow, or to human activities tipping the balance against forest.

In historic times, moorland has been much used for pasture and for digging peat as fuel. Large supplies of peat have made up for the scarcity of wood fuel in Scotland and Ireland. A skilled tradition of periodic burning has grown up to

maintain the pasture. In the past 200 years, moorland regions have lost human populations, but without forest returning. The main uses of moorland now are for grouse (*Lagopus scoticus*) and deer as game animals.

Buildings and Built-up Areas

Many plants and animals live on buildings, including some quite rare species: for example, the stork in Europe, which nests almost exclusively on buildings and structures, sometimes on platforms provided for it. In England, buildings and abandoned mines are the chief strongholds of bats.

Cities are often the chief concentrations of wildlife in their regions: well-known examples are Cambridge and Glasgow, which contain more wild plant species in a given area than anywhere else in their surroundings. This is because of the diverse habitats provided by gardens (despite the prevalent use of garden chemicals), buildings, and especially ruins and derelict land.

Derelict industrial land can be an important habitat. In England, the quarry that provided the excellent Barnack building stone is now one of the best examples of limestone grassland. Long-standing chemical contamination can produce its own ecosystems, especially where heavy-metal-tolerant plants have evolved.

Sacred sites develop in peculiar ways. In Japan, temples and shrines often own forests, which may preserve ancient trees and evidence of past management practices. In England, many churchyards are excellent habitats (Figure 13). They often contain their own peculiar types of grassland. Tombstones and the stonework of the church itself are important sites for rare lichens, especially in areas that lack natural rock outcrops.

The Rise and Fall of Historic Land-Use Patterns

Human intervention creates new ecosystems as well as destroying old ones. Cultural ecosystems are often complex, diverse, and stable. Sometimes they are modifications and extensions of ancient natural ecosystems. Chalk grassland, for example, is in some respects a prolongation in time of the grasslands of the glacial periods. Moorland is in some respects an extension of tundra into southern latitudes. Some, however, seem to be new creations: The author hesitates to guess what the habitat of the plant *Fritillaria meleagris* might have been before hay meadows had been invented.

Some conservationists regard ancient human intervention as destructive, like the modern logging of the Oregon redwoods or the early-modern ravaging of oceanic islands. Sometimes this was so: we would undoubtedly now disapprove of the destruction of almost all the native mammals of Crete by its early human inhabitants. Some interventions were experimental and unsustainable, like the prehistoric attempt to farm Dartmoor. Others may have been almost too gradual to notice, such as the erosion of tree cover on a common pasture.

The ecosystems of cultural landscapes could be preserved for centuries, both by ownership patterns and by deliberate

conservation. By AD 1350, some 94% of the forest of England had been converted to nonforest uses. Woodland management had been invented long before, probably for other reasons, but as forest became scarce, conservation practices gradually spread to the remaining forest. It may be no coincidence that the idea of sustained yield is first set down in writing in 1356. Many medieval wood-lots still exist, and are often now nature reserves: "Ancient Woodland" is a scheduled category in modern conservation.

Historic land-use patterns usually worked on a small enough scale to result in useful juxtapositions of habitats. They often perpetuated habitats for non-shade-tolerant plants and animals. Because of the glacial history of the past 2 million years, many species are adapted to nonforest conditions and are threatened by the advance of forests in interglacial periods. They would have fared particularly badly in the present interglacial, because of the widespread extinction of giant tree-breaking mammals. For example, the greatest concentration of endemic plants in Europe is in the Mediterranean, where nearly all of them are nonforest species.

Historic land-use patterns have been in retreat for some 250 years. Usually this was because of outside ideas and interventions, not because they were unsustainable. Commonlands were not destroyed because of the operation of the "Tragedy of the Commons:" the supposed tendency of communal systems to break down because each participant pursues his own short-term advantage regardless of the rights of other participants. That had already been foreseen, and the participants in most commons had drawn up rules of use to prevent it.

In the eighteenth century, multiple and especially communal land-uses became unfashionable. The only proper use of cultivable land (or land thought to be cultivable) was conventional agriculture, carried on by private owners in rectangular plots of not less than 10 acres. For uncultivable land the proper use was timber production organized by the state on the model of either French or German "scientific" forestry (depending on which state). Agricultural writers invented these ideas and bent the ear of governments to get them put into practice; they were not deterred if their schemes failed to work. In this way, the open fields of England were destroyed, and most of the heathland was converted into poor-quality arable. In countries where modern forestry was influential, such as Sweden, Germany, and Italy, most of the wood-pasture ecosystems were destroyed.

In the twentieth century there have been four contrasting processes: extension of cultivation (including plantation forestry) into areas not previously cultivated; mechanization of cultivation in areas already cultivated; urban development; and land abandonment. Often, as in Crete, all four occur almost side by side. They destroy existing seminatural ecosystems without creating an equivalent. A common feature is that the grain of the landscape is coarsened: the small-scale pattern of juxtaposed land uses is replaced by monotonous expanses of the same land use.

One consequence is loss of habitat for creatures that require more than one habitat: birds that feed in the open but nest in tree holes; insects whose larvae feed in rotten wood but whose adults need a nectar source; plants that are weakly competitive when growing in the open but do not flower in

Figure 13 Churchyards have a range of habitats from old grassland (important for reptiles and amphibians) to the stone and brick surfaces of the boundary wall, tombstones, and the church itself (lichens) and the thatched or tiled roof (bryophytes, flowering plants). *Rockland St. Peter, Norfolk.*

shade – all these were favored by the mosaic of historical land-uses, but not by what has replaced them.

Land abandonment does not re-create wildwood (wildwood either as it was before human intervention or as it would be by now had that intervention never happened). It tends to produce uniform expanses of even-aged, densely shading trees: the herbaceous plants of grassland, field edges, etc., disappear without being replaced by woodland herbs. In Mediterranean Europe, where secondary forest often consists of fire-adapted trees, the effect is a recurrent cycle

of fires, which destroy whatever escaped the increasing shade. Many conservationists disapprove of goats, but the consequence of removing goats is usually to convert a browsing-dominated landscape into a fire-dominated one (Figure 14).

Land-use has become polarized: for example, land is now either forest or pasture but not both. Most of rural Japan, for example, is forest, and the remainder is intensively cultivated rice fields. The forests are now little used, and within them are the remains of many historic ecosystems: coppice woods,

Figure 14 This was a goat-browsed landscape with patches of evergreen oak savanna and forest. It was taken over by foresters, who suppressed goats and planted pines (an ultraflammable tree). The inevitable result was a great fire. *Valor, Alpujarra, Spain.*

Figure 15 An old pollard larch (*Larix leptolepis*) in what is now forest. Its spreading habit proclaims that it was originally a freestanding tree in grassland. *Tateshima, Chino, Japan.*

wood-pastures (Figure 15), terraced rice fields, pine savannas, Japanese early-modern forestry, and the growing of the giant grass with which house roofs were thatched.

Forests, on the whole, have become denser as savannas infill, coppice woods grow up, and foresters encourage the growth of timber trees. The older trees in a forest are commonly more spreading than the younger ones, having grown up when they had more room. The author has seen examples in many countries from Canada to New South Wales, often in forests with little obvious human intervention.

An important innovation is the cult of tidiness: the urge among professional planners to destroy old quarries, spoil

heaps, ruined buildings, patches of roughland, and even old trees and neglected tombstones, on the grounds that the public might not like them – even though, in practice, derelict land is often a much-loved public amenity.

Implications for Biological Conservation

Some conservationists disdain cultural ecosystems on the grounds that they result from the “degradation” of wilderness ecosystems, especially forest. The only proper business of biological conservation (they say) is to preserve pristine

natural ecosystems where they still exist or to restore them where they do not.

However, this cannot be the whole purpose of conservation. In many parts of the world, such as England, ecosystems have been modified by human activity for much of the Holocene; not enough is known about pristine natural ecosystems to make restoring them a practical objective. Conservation depends on public interest, which it cannot retain if it is limited to remote wildernesses that few of the public ever see. It is unrealistic and impolitic to cut off biological conservation from other kinds of conservation: to separate the archeological interest in an earthwork from the biological interest in the vegetation growing on it. It is essential for students to gain a knowledge of how local ecosystems work before pronouncing on those of distant countries.

Wilderness philosophy often ignores the realities of archeology or vegetation history. In many countries, when a national park is scheduled, the authorities automatically expel the human inhabitants (however long and respectable their history), play down their part in the development of the landscape and ecosystems, and pretend that the park is wilderness. In Yellowstone National Park they even tried to efface all evidence that settlement had ever happened. In reality, few national parks lack human influence altogether; many of them are the last strongholds of precisely those old-fashioned land-uses that biological conservationists ought to support. (The National Trust, biggest landowner in the Lake District National Park in England, goes to much trouble to sustain farming and prevent land abandonment.)

Conservationists are tempted to start from theories of what natural ecosystems ought to be and to recreate them in the image of those theories. They regard large, continuous, mixed-aged forests of tall trees as natural and try to preserve those forests that most nearly approach that ideal. The notion owes more to climax theory and to foresters' notions of an ideal forest than to weighing the evidence of what particular natural forests were like; yet its influence leads to neglect of discontinuous forests, savanna, and forests of short trees, however remarkable.

Biological conservation has many aspects. Priority is rightly given to preventing logging of remote forests that have never been logged, whether or not later research shows that they are really wilderness. However, the real merits of cultural ecosystems should not be overlooked. Wildwood included a great diversity of ecosystems. Those that involved open ground often predominated during glaciations. When giant herbivores were exterminated, this probably made the forests more shady, and the survival of nonshade-bearing plants through

interglacials more difficult. Historic land management, to some extent, supplied the place of the missing elephants and restored the habitats of savanna and open ground. Modern changes tend to destroy historic ecosystems altogether or to replace them with uniform, very shady forest. Historic land-use patterns need to be respected and historic cultural ecosystems maintained. Conservationists rightly campaign against destroying trees in tropical rainforests. They often need to campaign against allowing trees to grow in unsuitable places near home.

Glossary

Comparative analysis Pattern-seeking across natural ecosystems based on the premise that existing gradients and variations generate regularities which can be discerned by statistical analysis of the composite aggregate, of component variables, or of mechanistic connections.

Complex adaptive system A system of multiple interconnected diverse elements whose localized interactions are subject to autonomous selection, leading to continual change and hierarchical structure.

Ecological stoichiometry The quantitative relationship between chemical elements (especially carbon, nitrogen, and phosphorus) arising from ecological processes and interactions such as nutrient acquisition, biomass formation, remineralization, trophic transfer, sedimentation, and dilution.

Macroscopic pattern Regularity observed at a scale higher than that of the interacting units, being the statistical or emergent expression of the ensemble arising from the components.

Multiscale analysis A change in the resolution or range of a measurement to evince a change in pattern.

Plankton functional types A classification of plankton according to commonly shared adaptive features such as physiological and morphological traits which lead in

combination to predictable ecosystem or biogeochemical functions.

Plankton size classes A classification of plankton according to size, based on the International System of Units prefixes of the approximate live weight in grams for successive logarithmic intervals of organism width or length: femtoplankton (0.02–0.2 μm), picoplankton (0.2–2 μm), nanoplankton (2–20 μm), microplankton (20–200 μm), mesoplankton (0.2–20 mm), macroplankton (2–20 cm), and megaplankton (20–200 cm).

Plankton trophic types A classification of plankton according to whether they obtain energy from light ("photo") or chemicals ("chemo"), whether they obtain electrons from water ("litho") or organic carbon ("organo"), and whether they obtain carbon from inorganic ("auto") or organic ("hetero") compounds, with the possibility of mixed modes ("mixo"): for example, photolithoautotrophy, chemoorganoheterotrophy, photoorganoautotrophy, photoorganoheterotrophy, and mixotrophy.

Power law A relationship that scales a dependent variable (Y) to an independent variable (X) through a normalization factor (a) and a power exponent (b) in the form $Y = aX^b$.

Scale The distance or time over which a significant change in some quantity of interest can be resolved.

Microscopic Organisms and Macroscopic Patterns

Marine Plankton

Marine plankton are pelagic organisms, motile or nonmotile, that are entrained by the prevailing movement of water. These biological entities range over many orders of magnitude in size from nanometer-scale viruses of the femtoplankton to meter scale gelatinous animals of the megaplankton. By numbers, biomass, and diversity, it is the microscopic forms of plankton that pervade the oceans. The majority of these are prokaryotes and unicellular eukaryotes. Global estimates of prokaryotic marine plankton indicate a stock of 10^{29} cells, a

biomass of over 2 Pg carbon, and a genetic richness of perhaps up to 2 million different kinds of taxonomic units. These bacteria and archaea, together with the smaller pool of eukaryotic algae and protists, constitute the foundation of pelagic food webs. In oxygenated waters, most microbial plankton are photolithoautotrophs, chemoorganoheterotrophs, or mixotrophs, but significant number of them also possess capabilities for photoorganoautotrophy or photoorganoheterotrophy. Thus, not only is there great diversity in size and form amongst the microbes, but also there is a wide range of metabolic functions. All other plankton, being metazoan, are chemoorganotrophs and depend ultimately on the microbes. Individually, plankton live short lives and

interact over short distances. However, they have collectively established the conditions for life over the entire Earth since the beginning of evolutionary time, and continue to maintain biospheric integrity through complex adaptations.

Patterns and Processes

In ecology, a pattern can be described as regularities in what we observe in nature; that is, they are widely observable tendencies (Lawton, 1999). Importantly, patterns can exist at various scales in time and space. A macroscopic pattern is one in which the regularity is observed at a scale higher than that of the interacting units. At each scale, the number of biological units is larger than that at the next higher scale. The expression of the ensemble in terms of the component units results in the pattern, which is called macroscopic. The study of macroscopic patterns in ecology is macroecology, and it can be stated as the enterprise of trying to infer laws of nature from the statistical manifestations of the many interacting biotic units of ecological systems (Brown, 1995).

A bulk effect, which is a statistical resultant of aggregating system components, is no less a macroscopic character than an epiphenomenon that emerges from underlying complexity, or one that appears out of constraints imposed from even larger scales. Thus, macroscopic patterns can arise from large number systems in which many independent, essentially identical components interact randomly to give system averages, which are stated in the formalism of statistical mechanics. Macroscopic patterns can also arise from systems in which intermediate numbers of components interact in structured and complex interrelationships. Plankton might be viewed as complex adaptive systems because the essential elements of such systems are in place: natural selection acting on individual components with diversity sustained through localized interactions yielding a subset for replication or enhancement (Levin, 1998). Indeed, macroecology might be considered a perspective on ecological complexity, whether one believes populations and communities to be complex adaptive systems, or simply to be the convenient assemblages of organisms selected for study (Brown, 1995).

In a strict sense, a macroscopic pattern refers only to that which is observed. It is a separate and much more difficult matter to understand the determinant, which is the process. Pattern seeking is an exercise in empirical observation, and the enterprise of large numbers often requires observation over extensive geographic areas and over prolonged durations. Biogeography and macroevolution are therefore sometimes implicated in macroecology, but macroscopic patterns need not necessarily inform about these disciplines. Understanding process through deduction is a part of the macroecological agenda; but it necessarily follows inductive insight gained from pattern detection.

Comparative Ecology and Macroecology

Comparative Analyses of Plankton Ecosystems

The study of macroscopic patterns is a well-established part of biological oceanography, even though the neologistic origin of macroecology is strongly based in terrestrial and avian eco-

logy. At a symposium held in 1956, Alfred Redfield addressed the imbalance of experiment and observation in marine biology and suggested that "to understand the distribution and abundance of life in the sea, the approach must be primarily statistical through the development of significant relationships between large quantities of observations on biological and physical events, occurring often in widely scattered places" (Redfield, 1960). Essentially, this is a prescription for comparative analyses of ecosystems, an approach that has since been extensively used in the study of plankton.

Some of the most common comparative analyses in aquatic ecology are bivariate relationships between plankton trophic groups (Gasol and Duarte, 2000). Plankton are adaptive and complex, so it becomes a simplification when single variables are chosen as surrogates for entire trophic groups. In principle, this simplification is not necessary for comparative analyses, but the demands for large number analyses require measurements that are operationally well defined and easy. For example, the entire photoautotrophic pelagos is often represented by the concentration of chlorophyll *a*. In many cases, this photopigment is not only an adequate and suitable surrogate for the diversity of unicellular algae and cyanobacteria, but is also a useful predictor variable amenable to widespread application. In other cases, however, the surrogate confounds process and obscures patterns. Generality at a high level of description comes at the expense of a loss in detail at a lower level.

Macroecology in Biological Oceanography

The spatial and temporal structures in plankton ecosystems are a fertile area for macroecological study because some aspects are accessible to easy measurement at many scales. For phytoplankton, if we do not restrict the definition of structure only to ecosystem rate parameters, but also admit state variables, then either the surrogate of chlorophyll *a* (and its many proxies such as fluorescence and ocean color) or direct counts of individual cells can provide useful information across many scales. In this way, horizontal distributions of phytoplankton can be studied from turbulent regimes of local environments (Platt, 1972) to biogeochemical regimes of the global ocean (Platt and Sathyendranath, 1999). The premise that phytoplankton distributions are under the broad control of abiotic forcing at regional and global scales allows the pelagos to be viewed in an ecological geography rather than in a traditional biogeography (Longhurst, 1998). In other words, areas of the ocean with common abiotic forcing might be expected to have similar ecologies (Platt *et al.*, 2005). Testing this premise with other plankton is more difficult because of limited data, but some progress can be seen in studies of heterotrophic bacterioplankton, which show marked contrasts at the largest scale of ecological domains (Ducklow, 2003). In the ocean, variations in physical forcing tend to increase with spatial and temporal scales. Red noise, so called, makes a dominant difference in the variance structure between marine and terrestrial systems, and is associated with stronger adaptive responses to long-term change in the ocean (Steele, 1985). Spectral analysis, as a statistical mechanical representation of ecological systems, has deep roots in phytoplankton studies

(Platt and Denman, 1975). Macroecology, it seems, has always been a part of biological oceanography.

Scales of Variability

Multiscale Analysis

The linkage of spatial and temporal variability is a long-standing concept in oceanography. Graphical representations of the variability in a measured quantity in the space–time domain are familiar to physical oceanographers, for example, the Stommel diagram, and to biological oceanographers, for example, the Haury–McGowan–Wiebe diagram (Haury *et al.*, 1978). In logarithmic fashion, time ranges from minutes to hundreds of thousands of years on one axis, space ranges from centimeters to tens of thousands of kilometers on a second axis, and biological variability is indicated on a third axis. These diagrams portray the overlapping hierarchy of patterns along the diagonal, stretching from small space–time scales to large space–time scales. They also convey the reality that what can be perceived is limited by the narrow space–time window through which observations are made. The search for macroscopic patterns is an exercise of increasing the scale of analysis.

In multiscale analysis, a systematic change is made to the scope of a quantity. Scope, which is the dimensionless ratio of extent to grain, expresses space or time as the number of

measured units adding up to the length of the investigation. For example, if plankton is collected from a site once every week (the grain) for a total duration of 14 years (the extent), the scope is 728 ($52 \times 14/1$). Various scaling methods exist to change the scope (Schneider, 2001).

Coarse Graining

The method of coarse graining takes the full extent of the weekly measurements and averages them within increasingly larger grain sizes, such as a month, a year, a quadrennial, and so on. An example is shown for time series of bacterioplankton and phytoplankton sampled weekly for 14 and 13 years, respectively (Figure 1). Averaging of raw measurements into increasingly larger grains reduces variance. In the example, at the largest grain of a year, all the weekly heterogeneity becomes unresolved, and the between-year heterogeneity decreases (Figure 1(d)). It then becomes meaningful to seek a long-term (macroscopic) signal from the annual averages unencumbered by the weekly noise. For the phytoplankton in this example, cell abundance has increased at a rate of 4% per year from 1993 to 2005. As the time series lengthens into the future, it should not be a surprise if annual variance were to increase since a larger extent encompasses more realized situations. Emphatically, this multiscale analysis demonstrates the difficulty of empirically detecting a

Figure 1 Multiscale analysis by coarse graining. Time series of phytoplankton and heterotrophic bacterioplankton abundance in Bedford Basin, Canada from 1992 to 2005. (a) Weekly measurements, (b) monthly averages, (c) seasonal averages, and (d) annual averages.

multiyear trend if either the grain size of raw observation is not small enough, or if the extent is not large enough.

Accumulating

Another method of changing the scale of analysis is to accumulate an increasing collection of samples. By always using the same operational procedure for collection, each sample may be considered an element in the set of all possible configurations. The more samples accrued, the higher the degree of aggregation. A herculean human endeavor of counting and identifying all 195,983 microphytoplankton cells in 1388 Mediterranean Sea samples, and all 1,111,859 such cells in 1144 Caribbean Sea samples by Margalef (1994) and his colleagues is a majestic exemplar. From these ensembles emerge an elegantly succinct pattern: $S(n) \propto n^{-1}$, which is to say that there is a simple power-law relationship between the number of individuals, n , and the number of species, S , represented by that particular number of individuals (Solé *et al.*, 2002). In other words, only a few species have large populations of individuals, but many species have small populations.

With electronic technology, it is possible to count picophytoplankton and nanophytoplankton with considerable ease. The detection of these cells is based on biooptical characteristics such as light scatter and photopigment autofluorescence. Bivariate diagrams plot each cell as a single dot on an $m \times m$ grid (where m is usually 256 or 1024) representing the position of the cell on the coordinate space of light scatter and pigment fluorescence. A subsequent cell that occupies the same coordinates makes the display dot darker in appearance. The result of analyzing a single water sample is a cytometric diagram showing the density of occupancy of the coordinate space. One such realization taken on a single day in 1996 detected several thousand cells (Figure 2(a)). Samples measured week after week (Figure 1) accrued over an entire year greatly increase the number of cells. A larger portion of the coordinate space is occupied by the yearly accumulation, and the cell abundance at occupied positions increases. At this annual level, there is an accrual of a few hundred thousand cells (Figure 2(b)). The procedure can be carried further to show accumulation of greater than a million cells at the quadrennial scale (Figure 2(c)), and finally to the extent of the entire 676-week time series (Figure 2(d)) during which 5 million cells have been counted. By pooling all fluorescence measurements at a given light scatter value into a single bin, the cytometric data can be displayed as univariate frequency histograms resembling cell-size spectra. Increasing the scale by accumulation transforms the heterogeneous single-week spectra (Figure 3(a)) to more homogeneous annual (Figure 3(b)) and quadrennial spectra (Figure 3(c)), and finally to the unitary 13-year spectrum (Figure 3(d)). As with coarse graining, accrual smooths out variance.

Macroscopic Assembly

Trophic Classification

One of the most enduring constructs in ecology is the trophic pyramid. Organisms are assigned to one, and only one, of a

small number of feeding categories, which are then arranged in food chain sequence, showing the importance of each trophic level in relation to those below and above it. Traditionally, the categories are primary producers (autotrophs), decomposers (bacteria), primary consumers (herbivores), secondary consumers (carnivores), and tertiary consumers (apex predator). Importance can be indicated by the number of individuals, by total biomass, or by energy flux. Trophic diagrams of energy are constrained by thermodynamics to have an upward pyramidal shape, but diagrams of numbers and biomass are free to assume other appearances, even inverted pyramid. Plankton biomass pyramids built of autotrophs (phytoplankton) and heterotrophs (bacterioplankton, microzooplankton, and mesozooplankton) have a tendency to be inverted in open ocean waters. This implicates both a fast turnover of phytoplankton and a tight consumer control of primary production (Gasol *et al.*, 1997).

A trophic pyramid might be considered a nonnested hierarchy. In other words, the apex predator in a marine food chain does not nest within it (as reducible components) all the carnivorous zooplankton, the herbivorous zooplankton, and the phytoplankton. Yet, the system is a hierarchy as defined by a system of communication where entities with slow behavior are at the top, while successively faster behaving entities occur lower in the hierarchy (Allen and Starr, 1982). In principle, the behavior of some nested hierarchies may be determinable if observations are sufficiently complete so that the parts can be added up. There are other properties of nested systems that could prevent this realization; but in any case, actual determinability in real ecosystems is likely unachievable. However, nonnested hierarchies are truly indeterminable because the entities are themselves quasi-independent wholes, with nested hierarchies within each (Allen and Starr, 1982).

For several reasons, the pyramid as described is less useful as a construct for plankton ecosystems than it once may have appeared to be. As a system that transfers mass and energy in a linear route from plants to herbivores to carnivores, the traditional pyramid fails to give explicit account to the microbial loop, which diverts primary production to heterotrophic prokaryotes (bacteria and archaea) and thence to phagotrophic protistan eukaryotes (microzooplankton). Microzooplankton is an important prey for mesozooplankton, so trophic linkage remains; but the microbes as a whole are a large respiratory sink, which greatly alters the dynamic functioning of the system. The pyramid also fails to recognize the viral shunt, which by recycling energy within the microbial loop becomes a futile path for any transfer to metazoans. Finally, the idea that an organism must be of a singular trophic type is too restrictive since mixotrophs are common.

Nevertheless, the partition of plankton into nominal trophic groups offers ecological insight that can be particularly robust in statistical terms. The structural relationship between trophic groups is most often represented by a linear model. As more ecosystems are progressively sampled, a greater degree of natural variability is encountered. Patterns formed by a large number of observations have more freedom to reveal nonlinear structures such as thresholds, boundaries, and inflections (Duarte, 1991). For example, the relationship between oceanic bacterioplankton and phytoplankton appears linear in regional ecosystems, and this is consistent

Figure 2 Multiscale analysis by accumulation. with known mechanisms of carbon flux between the interacting trophic groups. However, a global aggregation of these observations reveals a nonlinear constraint on the actualized expression, indicating a need for more descriptive details of other interacting components (Li *et al.*, 2004). Interestingly, with appropriate attention to statistical nuances, it may be possible to invert the problem and use cross-system information to investigate the structural relationship between variables within a single system (Prairie and Marshall, 1995).

Size Classification

Organism size has been a fundamental organizing attribute in plankton ecology since the early days of oceanography when

nets of different mesh size were used to selectively retain plankton. The fact that named plankton size classes (see Glossary) are arrayed in logarithmic series is tacit recognition of the importance of power-law scaling. As a means to manage complexity, power-law scaling of plankton size has much appeal because it portends consilience with many other natural systems. Metabolic rate is related to body size of organisms ranging from microbes to the largest vertebrates through a common power exponent whose value is generally (but not universally) taken to be < 1 . Although new evidence suggests that even suborganismal entities (mitochondria and respiratory complexes) may share the same exponent (West *et al.*, 2002), considerations of nonscalable components within a cell such as a minimum genome and biological membranes of constant thickness may imply a different power exponent for the

Figure 3 Multiscale analysis by accumulation. Size-frequency histograms of phytoplankton in Bedford Basin. (a) Four weekly measurements, (b) four annual accumulations, (c) three quadrennial accumulations, and (d) 13-year accumulation.

smallest picoplankters (Raven *et al.*, 2005). Notwithstanding the exact value of the exponent, metabolic scaling has given rise to various theoretical models deriving the distribution of organism abundance and biomass according to body size. All such models, implicitly or explicitly, address one of the most striking macroscopic patterns in pelagic ecology. This pattern, first anticipated by pioneering ecologists Charles Elton and Howard Odum, was demonstrated by observations made by Sheldon *et al.* (1972) showing that in the euphotic zone of oceanic regions, “to a first approximation, roughly equal concentrations of material occur at all particle sizes within the range from 1 to 10^6 μm , i.e., from bacteria to whales.”

Trophic models of plankton size spectra take apparent universal metabolic scaling within each trophic level, assign a large difference to the body size of predator and prey, and dissipate energy at each feeding step (Kerr, 1974). Biomass invariance across logarithmic size classes can indeed be an outcome of these models (Brown *et al.*, 2004). Microbial ecologists who view the plankton system at a lower hierarchical level may find the simplifications to be unjustified. They see primary producers virtually span the entire size range from picoplanktonic *Prochlorococcus* to macroplanktonic *Trichodesmium*; they see a considerable number of unicells functioning at more than one trophic level; and they see a majority of protistan grazers only slightly larger than their prey, and therefore in a closely adjacent logarithmic size class.

An alternative model of unidirectional biomass flow from small to large organisms (Platt and Denman, 1978), inspired by the cascade of turbulent energy from small to large wave numbers, replaces discrete trophic levels with a size continuum. The model predicts a slight decrease of biomass with size. This has been confirmed in both the North Pacific (Rodríguez and Mullin, 1986) and the North Atlantic (Quiñones *et al.*, 2003) by high-resolution spectra carefully constructed by merging windows of observation derived by different plankton measurement technologies. A strength of this model is that it can be integrated analytically to yield metabolic information for the community as a whole, therefore providing constraints on function based on structure. A difficulty, pointed out by Platt himself, is the need to reconcile the microbial loop, which is a counterflow of material against the general direction.

At an adequately high level of aggregation, such as achieved by accumulating inventories from many different habitats acquired over many years into a “superspectrum,” a similitude appears toward a system in which biomass is shared randomly among size classes without preference (Rodríguez, 1994). This type of power-law distribution suggests another way to regard plankton size spectra, namely as a case of scale invariance or self-similarity. In other words, plankton systems may not have any characteristic scale and the components may be organized according to dynamics that cross scales.

Self-similarity thus provides a means to extrapolate between scales.

A notable example of power-law phenomena in plankton can be found in the microbes where, coincidentally, trophic and biomass flow concepts are least clear-cut. In this limited range at the low end of the size spectrum, not only does a power law describe the community (Li, 2002), but also a related power law with the same scaling exponent also describes the relationship between abundance and size for the components: heterotrophic bacteria, *Prochlorococcus*, *Synechococcus*, other picophytoplankton and nanophytoplankton (Rinaldo *et al.*, 2002). The individual distributions are strongly peaked, but partial overlap in size from one to another results in smoothed ensembles. Where one group (e.g., *Prochlorococcus*) might be missing, there might be more of another (e.g., heterotrophic bacteria) or a broadening of the distribution of another (e.g., *Synechococcus*) to fill the gap (Cavender-Bares *et al.*, 2001). Individuals interact with each other locally but become organized into aggregates that appear regular. The size structure of the phytoplankton community may at times be strongly regulated by factors such as competition, grazing, infection, sinking, and physical aggregation, but it also seems that size scaling of cellular nutrient requirements and growth alone can suffice to produce widely observed features such as the power-law relationship, the dominance of small phytoplankton cells in oligotrophic oceans, and the relative increase in large phytoplankton cells under eutrophic conditions (Irwin *et al.*, 2006).

Functional Classification

In terrestrial ecology, plant functional types are sets of species with similar responses to the environment and with similar effects on ecosystem functioning. In essence, this classification seeks functional commonalities in life forms that cut across phylogenetic, autecological, and allometric diversities. Extending this concept to phytoplankton has resulted in detailed assembly rules for freshwater assemblages (Reynolds *et al.*, 2002) and marine dinoflagellates (Smayda and Reynolds, 2001). In these works, the primary emphasis has been on recognizing shared adaptive features that favor a close association of certain organisms well disposed toward certain habitats. These organism associations are mapped against a matrix of habitat gradients (nutrients, irradiance, and water turbulence) to reveal a pattern at a macroscopic level. Functional classification is a polyphyletic approach that arranges organisms according to their biological attributes and sensitivities, which are associated with particular habitat conditions. But even so, proceeding through a hierarchical filter to match the traits of class, genus, and species against habitat conditions, it is still not possible to predict at a low level (even if all traits were completely known) because selection is ultimately stochastic.

The concept of plankton functional types is similar to plant functional types, but oceanographic application emphasizes common effects on ecosystem functioning over common responses to environment. A prospectus for assessing the biogeochemical impact of plankton activities recognizes 10 provisional types: picoheterotrophs, picoautotrophs,

phytoplankton nitrogen-fixers, phytoplankton calcifiers, phytoplankton dimethylsulfide producers, phytoplankton silicifiers, mixed phytoplankton, protozooplankton, mesozooplankton, and macrozooplankton (Le Quéré *et al.*, 2005). This is clearly a mixed classification with some elements closely similar to trophic and size classes. Nevertheless, the idea of functional diversity is well accepted. Plankton functional types, appropriately clustered or ordinated, occupy an ecological trait space where the functional distance between types may be quite different from traditional measures of species differences (Weithoff, 2003).

Biogeochemical modeling of plankton functional types at the global scale requires sufficiently well-understood autecologies, a realistic type classification, and robust parameterizations: these are requirements perhaps not well met at present (Anderson, 2005). Nevertheless, it is understood that macroscopic patterns of functional types are a powerful way to study community structure. As an example, phytoplankton silicifiers, which are largely diatoms (but may also include silicoflagellates), can be indicated by their pigment composition or their spectral absorption characteristics. Inferences made from the broad distributions of fucoxanthin (measured by chromatography) and a water-leaving reflectance indicator (derived from satellite data) are consistent with known features of diatom distributions (Platt *et al.*, 2005). Although neither analytical chemistry nor spectral radiometry is incisive enough to provide an irrefutable diagnostic of diatoms, spatial mapping of proxy indicators allows the study of some plankton functional types at the large scale. Other plankton functional types have also been detected by satellites. These include calcifiers that detach high-reflectance coccoliths (Brown and Yoder, 1994), nitrogen-fixing *Trichodesmium* cyanobacteria that have a relatively unique spectral signature of high backscatter from gas vesicles, combined with the absorption and fluorescence of phycoerythrin (Subramaniam *et al.*, 2002), and bioluminescent bacteria which continuously emit light when concentrations of autoinducer are locally high (Miller *et al.*, 2005).

Phylogenetic Classification

It is in the sense of phylogeny that biological diversity is most widely understood. The arrangement of organisms according to their evolutionary relatedness in a nested hierarchy of taxonomic ranks is the basis on which marine autecology, conservation, and resource management is generally conducted. Many general ecological theories are strongly grounded in evolutionary relationships between species; therefore, it seems expedient to explore macroscopic patterns of plankton in that framework. However, to a considerable extent, those theories rely on human perception of morphology and lifestyle as a guide to differentiating between organisms. This guide fails us at the small scales of microbial plankton because organisms with a high ratio of surface area to volume appear to converge on relatively uniform morphological shapes such as spheres and rods. When organisms are very small, adaptive adjustments largely appear within the living volume rather than at the surface. Whereas macrobes tend to be diverse in shape and surface embellishments, microbes tend to be

diverse in metabolism and intracellular functionality. The nanoplankton are poised between the femtoplankton and picoplankton where the concept of morphospecies is conceded to be virtually untenable, and the microplankton, mesoplankton, and macroplankton where the concept is at least of arguable validity.

In microplankton and larger plankton, there is sufficient apparent confidence in taxon recognition of particular forms of diatoms, dinoflagellates, copepods, foraminiferans, and euphausiids that global distributions of these and others can be mapped for biogeographical study. Large-scale distributions of calanoid copepods are particularly well documented. Although taxonomic richness, evenness, and distinctness all decline from the tropics to the poles, they do so in different manners that are best explained by patterns of primary and secondary production consistent with Longhurst ecological geography (Woodd-Walker *et al.*, 2002). From the Continuous Plankton Recorder database, the information on greater than 100 taxa of calanoid copepods is sufficiently extensive in space and intensive in time that diversity can be examined in large contiguous ocean regions at diel, seasonal, and annual scales (Beaugrand and Ibañez, 2002). These multiscale considerations lead to a view that calanoid diversity is mainly regulated by temperature, hydrodynamics, stratification, and seasonal variability of the environment. But even so, a taxon as familiar as *Calanus* still cannot be regarded as taxonomically well described (Longhurst, 1998). In phytoplankton, when the richness of recognized species is examined in relationship to the surface area of the ecosystem, the familiar species-area power law is found, with an invariant exponent that spans many orders of magnitude in spatial extent (Smith *et al.*, 2005). Observations, or experiments, at one scale can therefore be used to inform at other scales. However, as with zooplankton, the taxonomy of even familiar species such as the diatom *Skeletonema costatum* may need revision (Sarno *et al.*, 2005).

In picoplankton (bacteria, archaea, and picoeukaryotes), the concept of species is vague but biological diversity can be inferred from nucleic acid sequences. "The individual is where the gene meets the environment" (Levin *et al.*, 2001); so if gene phylogeny equates to organism phylogeny, then genetically defined organismal units can also be expected to have a macroecology. Plankton phylogenetic trees are most commonly constructed from the small subunit ribosomal RNA gene. The structure and topology of the trees indicate a high degree of novelty and diversity in marine microbes. Were phylogenies better visualized as webs rather than trees, for example, because of prevalent lateral gene transfer, it would not change present consensus that the smallest organisms are also the most diverse.

In fact, the extent of diversity is even greater than that indicated by the dissimilarity of single genes. There is microdiversity. A group of coastal bacterioplankton showing nearly identical ribotype identity to *Vibrio splendidus* was estimated to consist of at least a thousand distinct genotypes (Thompson *et al.*, 2005). Similarly, oceanic bacterioplankton off California revealed greater than a thousand lineages from three clusters alone (Brown and Fuhrman, 2005). Some of this extensive diversity may be neutral with no selective advantage in the ecological context. Microdiverse clusters are thought to arise from periodic selection, but intracluster competition is not

strong enough to sweep (purge) members from the group. Yet, in at least one group of marine bacterioplankton, phylogenetically discrete clusters denoted by highly similar gene sequences are represented by ecologically differentiated units. These so-called ecotypes display different cellular characteristics, allowing them to partition environmental gradients in the ocean. In the photoautotrophic cyanobacterium *Prochlorococcus*, ecotypes are distributed in the ocean with respect to temperature, light, and nutrients in accord with functional capabilities conferred by their respective genomes (Johnson *et al.*, 2006). The global basin-scale distribution of *Prochlorococcus* ecotypes at the sea surface is consistent with prevailing environmental conditions resulting from physical oceanographic structuring of the water column (Bouman *et al.*, 2006).

The level of taxonomic resolution at which biogeographic and macroscopic patterns become evident is important in understanding evolutionary and community assembly processes. Genetic and genomic characterization of plankton suggest that some of the most finely resolved taxonomic units may not be distributed in random fashion. It follows that large-scale patterns should be discernible at higher taxonomic levels. At the genus level, the two marine cyanobacteria *Prochlorococcus* and *Synechococcus* have been mapped extensively in the ocean on the operational basis of cytometric characteristics. In the three Southern Subtropical Gyres (Bouman *et al.*, 2006), the surface distributions of the two genera are antiparallel (Pacific and Atlantic Oceans) or parallel (Indian Ocean) to each other (Figure 4(a)). In a bivariate plot of cell abundances, the data pairs seem to lie within a triangular polygon (Figure 4(b)). The orientation of the polygon indicates a large range of possible densities for *Prochlorococcus* at high densities of *Synechococcus*, but only a restricted high range for *Prochlorococcus* at low densities of *Synechococcus*. At the within-gyre scale, different processes evidently regulate the interaction between the two genera. At the larger between-gyre scale, there is a simple negative correlation between basin-averaged abundances of *Prochlorococcus* and *Synechococcus* in the order of Indian Ocean to Atlantic Ocean to Pacific Ocean (Figure 4(b)). This niche complementarity, earlier noted by Chisholm (1992) at a different spatiotemporal scale, is evident at a level of the taxonomic hierarchy higher than that of the interacting units, which are presumably the ecotypes or lower-level genomic variants. A decrease in the numerical abundance of *Prochlorococcus* is not fully offset by an increase in *Synechococcus*, but cells of the former are somewhat smaller on average than those of the latter, so there is a degree of ecological homeostasis in the combined cyanobacterial biomass.

It seems that different taxa can coexist by being sufficiently different or by being sufficiently similar. Taxa repulsion occurs when competition excludes others of moderate similarity. On the other hand, taxa attraction occurs when others are similar enough to avoid competition and results in self-organized clustered niches, a so-called paradox of the clumps (Nee and Colegrave, 2006). As evidence, the frequency distribution of phytoplankton species in Dutch lakes appears to be clustered along a niche axis defined by cell volume (Scheffer and van Nes, 2006). *Prochlorococcus* and *Synechococcus* share similar positions in the food web, physical cell size, dominant metabolic capabilities, and cellular biochemistry. For these

Figure 4 Abundance of *Prochlorococcus* and *Synechococcus* in the Southern Subtropical Gyres. Triangular polygon is drawn by eye to envelop the data cluster.

picoplankton, the phylogenetic perspective becomes intimately enmeshed with those based on trophic linkages, size allotment, functional performances, and indeed also with biotic elemental composition.

Stoichiometric Emergence

All living beings are made of the same few classes of biomolecules (e.g., proteins, carbohydrates, lipids, nucleic acids,

nucleotides, and pigments), which are constituted from the same few elements, of which the three major ones are carbon (C), nitrogen (N), and phosphorus (P). A consideration of the C:N:P stoichiometry of plankton is in effect a multiscale analysis from elements and molecules up through the biological hierarchy to populations, communities, ecosystems, and even ultimately to the biogeosphere (Sterner and Elser, 2002). In this sense, ecological stoichiometry is the quintessence of macroscopic emergence from microscopic organisms. Despite perceived

biodiversity and biocomplexity in plankton systems, there is apparent biosimplicity in the stoichiometric equivalence of oceanic plankton biomass and deep dissolved inorganic nutrients in the atomic ratio of 106:16:1, well known as the Redfield ratio. The concept of an elemental composition common to the living and nonliving parts of the Earth is alluring because it lends easily to a teleological metaphor of the biosphere as a super-organism on which selection acts. However, as it is most widely understood, selection acts at a much lower level. It is the genomic instructions within individual organisms that provide controlling directions. Accordingly, the observed stoichiometry of marine seston is a high-level pattern resulting from nested processes leading from fast molecular biology to slow biogeochemistry; it is not a Gaian homeostasis (Levin, 2005).

The concept of a common elemental composition in plankton is useful for biogeochemistry because the laws of matter conservation and stoichiometric proportions allow nutrient inventory to be balanced amongst the major elements and also between the biota and the water. However, because the Redfield ratio is a macroscopic pattern, it may not necessarily be robust at local scales, for example, when used to calculate a nonsteady-state drawdown of dissolved nutrients from observed local biomass accumulation in multiphyletic plankton assemblages (Figure 5). The Redfield ratio is an empirical statistical average (Figure 5(a)) and not a

fundamental biochemical constraint. Stoichiometric plasticity is possible in photolithoautotrophs because the elements are obtained from disparate soluble inorganic forms (e.g., bicarbonate, nitrate, and phosphate) whose supplies are not necessarily coupled. Indeed, phytoplankton has a considerable capacity for intracellular storage of excess nutrients. By contrast, heterotrophs obtain their elements together in pre-formed food items. If there is stoichiometric similarity between an organism and its resources, then there is some degree of homeostasis (Sterner and Elser, 2002). In this respect, there is a distinction between autotrophs and heterotrophs: Homeostasis is less evident in phytoplankton than in chemooorganotrophic bacterioplankton and zooplankton.

Organisms, especially autotrophs, vary considerably in elemental composition. Systematic phylogenetic differences in C:N:P exist between major superfamilies of phytoplankton, indicative of ancestral phenotypes (Quigg *et al.*, 2003). Furthermore, microalgae exhibit considerable physiological plasticity of C:N:P in response to nutrient and light conditions (Geider and La Roche, 2002). The smallest cyanobacteria (*Prochlorococcus* and *Synechococcus*) are characterized by very high C:P ratios due to low cellular P (Bertilsson *et al.*, 2003). Under P-limitation, most of this element in the cyanobacteria is found in DNA, a nonscalable cell component that constrains both minimum cell size and elemental stoichiometry

Figure 5 Time series of plankton and nutrients in Bedford Basin. (a) Particulate C:N atomic ratio showing the similarity of the average value to the Redfield ratio, (b) inorganic nitrogenous nutrients, (c) chlorophyll *a* concentration, and (d) numerical abundance of phytoplankton and heterotrophic bacterioplankton.

(Raven, 1994). Exponentially growing phytoplankton depend on intracellular growth machinery such as ribosomes which have a low N:P ratio; conversely, near-equilibrium slow-growth phytoplankton depend on resource-acquisition machinery such as nutrient-uptake proteins and chloroplasts which have a high N:P ratio. The appropriate mix of all these stoichiometric types results in the Redfield ratio (Klausmeier *et al.*, 2004). Oceanographic and atmospheric regimes that shift the relative availability of nutrients to phytoplankton may alter stoichiometric steady states, which might be discernible at regional and global scales.

Temperature Dependence

From Single Molecules to Biochemical Kinetics

Temperature affects the velocity of biochemical reactions which drive organism metabolism. Statistical thermodynamics is in essence a macroscopic rule used to predict the effects of temperature on chemical reactions. In an ideal gas at thermal equilibrium, it is impossible to describe the kinetic energy associated with each individual molecule, but Maxwell-Boltzmann distribution law shows that the probability of a molecule occupying a kinetic energy E is proportional to $e^{-E/kT}$ where k is Boltzmann constant (8.62×10^{-5} eV K⁻¹) and T the system's absolute temperature (K). There is an interesting resemblance between what this law represented (a bridge between microscopic physicists interested in single molecule dynamics and macroscopic physicists interested in whole systems dynamics) and the aim of macroecology as a discipline linking ecophysiology and community ecology.

Implicit in Maxwell-Boltzmann equation is the fact that as temperature increases the proportion of molecules with sufficient kinetic energy to react increases. This ultimately led Svante Arrhenius to formulate that the temperature dependence of reaction kinetics should scale as $e^{-E_a/RT}$ where R is the gas constant (8.31 J mol⁻¹ K⁻¹) and E_a is the activation energy of that particular reaction; reactions with higher E_a show stronger temperature dependence. The difference between Boltzmann's factor and Van't Hoff-Arrhenius equation is just that the former uses particle units (E in eV and k in eV K⁻¹) while the latter uses the molar scale (E_a in J mol⁻¹ and R in J mol⁻¹ K⁻¹). Because k and R are related by $k = R/(N_A \times j)$, where N_A is Avogadro constant ($N_A = 6.022 \times 10^{23}$) and a j conversion factor from electronvolts to Joules ($j = 1.602 \times 10^{-19}$ J eV⁻¹), both expressions have the same value. The more intuitive Q_{10} constant results from simplification of Van't Hoff-Arrhenius equation (Gillooly *et al.*, 2002).

From Biochemical Kinetics to Whole Organism Physiology

A second scaling step is needed to apply Boltzmann's-Arrhenius equation to the response of whole organism physiological rates to temperature. Although Boltzmann's-Arrhenius equation has been widely applied to biological systems, just recently the activation energy measured for whole-organism rates has been related to the activation energy of the main biochemical reactions that drive organism physiology (Gillooly *et al.*, 2001). Metabolic scaling theory proposes that because organism metabolism is mainly driven by mitochondrial respiration, the temperature dependence of

adenosine triphosphate (ATP) synthesis should determine the temperature dependence of whole-organism metabolic rate with an average activation energy for both processes close to 0.65 eV (or 62.7 kJ mol⁻¹) (Gillooly *et al.*, 2001). Although whole-organisms greatly depart from the ideal gas conditions for which Boltzmann's-Arrhenius equation was formulated and more complex explanations have emerged, the similar activation energy at both levels of organization is quite remarkable. For planktonic heterotrophs, whose metabolism is mainly driven by the synthesis of ATP, the activation energy for both respiratory (Lopez-Urrutia *et al.*, 2006) and growth rates (Rose and Caron, 2007) is close to the predicted value of 0.65 eV. But the temperature dependence of the metabolic rates of photosynthetic plankton has long been recognized to be lower than that of heterotrophs (Eppley, 1972) with values ranging from 0.29 to 0.39 eV (Lopez-Urrutia *et al.*, 2006; Rose and Caron, 2008). Allen *et al.* (2005) argued that the lower temperature dependence of land-plant photosynthetic rates (0.32 eV) is due to the kinetics of rubisco carboxylation and photorespiration. As temperature increases photorespiration increases relative to carboxylation thus reducing net carbon gain. The applicability of Allen *et al.* (2005) explanation to marine plankton depends on the assumption that CO₂ supply to Rubisco in marine plants, which have different diffusive characteristics and carbon concentration mechanism (Yvon-Durocher *et al.*, 2010), does not modify this theoretical explanation.

From Organisms to Communities, Biogeochemical Cycles, and Biodiversity

Regardless of the theoretical basis for the differential temperature dependence of the metabolic and growth rates of autotrophs and heterotrophs, the implication for to marine plankton community dynamics and biogeochemical cycles are far reaching. Huntley and Boyd (1984) showed that the zooplankton to phytoplankton production ratio would increase as temperature increases. Rose and Caron (2007) argued that phytoplankton blooms might occur more frequently in cold waters because the growth of grazers will be much lower than the growth of phytoplankton as temperature decreases. Laws *et al.* (2000) showed that the proportion of primary production exported to the deep increases with decreasing temperature because, at cold temperatures, the growth rates of heterotrophic decomposers are much lower so most organic matter is exported before it can be decomposed. Lopez-Urrutia *et al.* (2006) scaled the differential temperature dependence of planktonic respiration and photosynthesis to the metabolic balance of whole plankton communities and showed that as temperature increases the ratio of community production to respiration decreases.

Through its effects on organism metabolic rates, temperature also affects community structure. Higher cell division rates with increasing temperature might be responsible for the stronger DNA evolution and speciation rates observed in planktonic foraminifera toward the tropics (Allen and Gillooly, 2006). This kinetic energy hypothesis plays a fundamental role on the observed temperature dependent global patterns of marine biodiversity both in planktonic and other marine communities (Tittensor *et al.*, 2010).

Regional and Global Change

In addressing societal concerns for which plankton ecology is relevant, the dominant patterns are arguably to be sought at the macroscopic level. At this level, we will not always have both pattern and process firmly in place before responding to calls for prediction. Climate change, ecological regime shift, fisheries reallocation, and biodiversity loss occur across multiple scales, but impacts are most consequential at decadal and longer timescales, at large regional and global spatial scales. Modern management of marine resources based on ecosystem considerations requires us to look for evidence and impact of plankton change at the whole system level. Plankton, at least the small ones, live for only days or weeks. Thus, there is a need to link local interactions with regional–global patterns.

Such a linkage can be made when a testable theory is supported by sufficient data. The apparent universal scaling of biological attributes with body size is an important macroscopic pattern. Another is the dependence of metabolic rates on temperature and light (for phototrophs). Together, they underlie a general metabolic theory (Brown *et al.*, 2004), which scales individual rates of photosynthesis and respiration of constituent plankton organisms to ecosystem carbon flux rates of primary production and community respiration (López-Urrutia *et al.*, 2006). Photosynthesis is less dependent on temperature than respiration, and this leads to a prediction that the balance of biogenic carbon flux could be altered by climate change: Less CO₂ would be captured in the surface ocean as temperature increases.

Rules of community assembly prescribe the successional development of populations over a year. In the sea, unlike on land, the scales of variability are such that changing community patterns fit well in the physical context of hydrodynamics (Steele, 1998). Temperature, being an important determinant of both cell metabolism and water column stability, as well as an indicator of seasonal progression and climate change, is an ecosystem driver acting across many scales. Thus, it is perhaps not astounding, but remarkable nevertheless, that over a large region of the temperate and subarctic northwest Atlantic Ocean, there is a coherence in the wax and wane of phytoplankton cells over the annual cycle that is aligned by temperature (Li *et al.*, 2006a). By this rule, phytoplankton are not assembled according to taxonomy, size, or functional attribute, but only by virtue of being individual particulate autotrophic entities. In other words, it might be construed that the molecular basis for trophic mode is ascendant over any particular organismal form under these conditions.

Seasonal cycles recur annually, but the question is whether phase and amplitude remain the same from year to year. There is some evidence that such phenological change is occurring in plankton groups of the North Sea (Edwards and Richardson, 2004), with the implication that a temporal mismatch across trophic levels signals a decoupling of ecosystem components. On the Nova Scotian Shelf and Labrador Sea, there is other evidence that the seasonal means of phytoplankton biomass have been increasing in some areas, but decreasing in others. Indeed, it seems that these multiyear trends have propagated to the heterotrophic bacterioplankton because they also exhibit these trends: a case of coherent sign switching in the direction of long-term change (Li *et al.*, 2006b). Generation times of

phytoplankton and bacterioplankton are not greatly dissimilar, but become increasingly disparate from those of primary, secondary, and tertiary consumers at higher trophic levels. Do signals propagate through many levels with fidelity? A continental shelf ecosystem monitored for 40 years appears to show trophic cascades across four levels: large-bodied predators (benthic fish and seals), forage species (pelagic fish and macroinvertebrates), herbivorous zooplankton (calanoid copepods), and phytoplankton (green seston) (Frank *et al.*, 2005). This marine ecosystem is highly complex, and thus the signature of top-down control in the form of simple trophic cascade can be viewed as a macroscopic pattern. The actual details of grazing, forage, and predation are not important in a multidecade trend.

The enterprise of science, like nature, is hierarchical. International consortia work toward a capacity for global ecology; national networks are placed to embrace regional interests; and local alliances exist to address immediate concerns. However, a space–time hierarchy of institutional management of marine resources will not necessarily ensure appropriate normative behavior because human and ecological dynamics are mismatched in scale (Rice, 2001; Ehrlich and Levin, 2005). Moreover, multiscale considerations will inevitably be confronted by ecological fungibility (Steele, 1998), which is the substitutability of one entity by another of equal value or utility. Thus, at some level, the differences in biological patterns caused by historical contingencies and contemporary environmental factors become moot. If fungibility can be expressed in terms of energy flux, allometric linkage, adaptive attributes, functional performance, diversity indices, elemental balance, or other such concepts, then we may be able to see evidence of laws in ecology (Lawton, 1999). Part of the macroecological agenda is to delineate the range of natural variability in given ecosystems so that outliers may be identified, even if the process constraints on natural limits are not yet fully understood. From a management perspective, these limits may suggest points of natural thresholds that trigger precaution toward undesired system states. To describe how a large continental shelf ecosystem has devolved from one regime to another using indicators of ocean climate, plankton, invertebrates, fish, and human influence, and then to predict a potential fishery collapse in an adjacent ecosystem within a decade (Choi *et al.*, 2005) is a bold and consequential test of the empirical approach.

Concluding Remarks

Biological diversity is conceptualized by assigning living entities to different categories. Our perception of meaningful categories is based on what we observe. By and large, we observe whole organisms, namely the units that house the genes. However, it is possible to consider, and in fact construct by technology, an entire plankton community as the sum of all constituent genomes, a metagenome. Sequencing of the community genome yields information on ecological structure, function, and diversity that crosses multiple levels of the conventional biological hierarchy. Although such ecogenomic studies are nascent, comparative ecosystem analyses of metagenomes will undoubtedly yield patterns of macroscopic organization. Macroecology, by its holistic nature, is sometimes seen as an approach to rise above the repeating cycle of

data-intensive reductionism. A multiscale approach enables emergent patterns to consolidate myriad historical contingent events. Seemingly inexhaustible biodiversity can be telescoped to elegant biosimplicity.

Mangrove Ecosystems

Peter J Hogarth, University of York, York, UK

Glossary

Aerenchyma A spongy plant tissue composed largely of air spaces enabling gas exchange to take place by diffusion in underground mangrove roots.

Aerial roots In mangrove species such as *Rhizophora*, roots branch out from the stem some distance above the soil surface. Lenticels (pores) in the aerial portion of these roots enable gas exchange to take place, through aerenchyma tissue, with the respiring underground portions of the root.

Mangal A term sometimes used to specify the mangrove habitat as a whole as opposed to “mangrove” applying specifically to the trees themselves. For the most part, however, mangrove is considered to apply to both trees and habitat.

Pneumatophores In some species of mangrove, such as *Avicennia* and *Sonneratia*, underground roots spread laterally from the main stem. Pneumatophores grow vertically from these, typically standing 10–20 cm above the soil surface, enabling gas exchange to take place with the underground roots.

Pseudofecal pellet Fiddler crabs and their relatives collect soil with their mouthparts, separate organic particles from mineral components by a complex flotation process, ingest the former, and discard the latter in the form of compact pellets. These are known as pseudofecal because, although extraction has taken place, the waste material has not passed through the gut.

Mangrove Trees

Currently, the total mangrove area in the world is estimated at 170,000 km². They are the principal source of primary productivity in such areas. By their presence, they also provide shelter for other organisms. Mangroves are therefore the energy base, and physical substrate, of an often complex and diverse ecosystem. Mangrove faunas, to a unique extent, comprise organisms of both marine and terrestrial origin (Morrisey *et al.*, 2010; Spalding *et al.*, 1997; Stafford-Deitsch, 1996).

The Mangrove Habitat

The mangrove environment is a demanding one. Typically, mangroves are regularly inundated by tides and are therefore usually in a permanently waterlogged state. The tidal water is saline, so mangrove trees have the problem of coping with salt and acquiring sufficient water against an osmotic gradient. In hot climates, evaporation may make the salinity even greater than that of seawater. In the Indus Delta (Pakistan), for example, the prevailing salinity may be as much as twice that of seawater. Among the vascular plants, only mangroves flourish in such an inhospitable environment (Figure 1).

Figure 1 Mangroves (*Avicennia* and *Rhizophora*) fringing a tidal creek in the Indus Delta, Pakistan.

Mangroves are defined physiologically as trees that can survive in the mangrove habitat, or mangal. The term is not a taxonomic one, nor does it indicate phylogenetic divergence from a common mangrove ancestor. The approximately 50 species generally recognized as mangroves belong to 20 genera in 16 families, although two families, *Avicenniaceae* and *Rhizophoraceae*, dominate in number of species (as they do also in abundance) (Table 1). In most cases these genera and families also contain nonmangrove members. Mangrove species have evolved their specialist features as the result of convergent evolution, and mangrove attributes have probably evolved independently at least 15 times.

In addition to true mangrove species, there is also a loosely defined category of mangrove associates. These are species often occurring in mangrove habitats but which also occur elsewhere. Some are found only at the landward margins of the mangal, whereas others, such as creepers and lianes, have their roots above the intertidal zone but invade the mangal by using the mangrove trees purely for support. Other plants associated with mangrove trees are epiphytes, which include ferns and the “ant-house” plants (*see* Insects), and parasitic mangrove mistletoes (Field, 1995; Hogarth, 2007).

Adaptations to the Mangrove Environment

Salinity

Three principal mechanisms enable mangrove trees to survive saline environments. Some species exclude salt at the root surface while continuing to take in water. In *Aegiceras* and *Avicennia*, up to 97% of the salt is excluded, apparently by a physical rather than a metabolic mechanism. This has the effect of locally increasing the salinity of the soil around the

roots, with implications for other organisms: mangrove trees modify their environment as well as respond to it. In other instances, trees take in salt but sequester it within cells in such a way that sensitive metabolic processes are protected from contact with excessive salt concentrations. Finally, several mangrove species secrete excess salt, at considerable metabolic cost, from specialized salt glands on their leaves. Many mangrove species use a combination of these mechanisms, as shown in Table 2.

Waterlogging

The major problem of waterlogged soils is lack of oxygen. Underground roots, like all tissues, require oxygen for respiration. In a normal soil, gas exchange takes place readily through air-filled spaces between soil particles. In water, the rate of diffusion of oxygen is very low, and in consequence waterlogged soils are generally virtually lacking in free oxygen. One of the most widespread mangrove trees, *Rhizophora*, adapts to such anoxic soils by keeping much of the root mass above the mud surface, surrounded by air. The stretches of these aerial roots (Figure 2) close to the soil carry numerous gas-exchange pores, or lenticels, whereas the underground portions are honeycombed with air-filled spaces.

This air-filled tissue, or aerenchyma, is also a feature of *Avicennia* and *Sonneratia*, whose roots are horizontal and close to the surface. These species respire by growing numerous pencil-like pneumatophores, which protrude above the mud surface and allow gas exchange with the underground tissues (Figure 3). Pneumatophore growth is facultative: the less waterlogged the soil, the lower the pneumatophore density. In the extreme and atypical case of *Avicennia* growing in sand between the Egyptian Sinai desert and the sea, the soil is so well oxygenated that no pneumatophores develop.

The aerial roots of *Rhizophora* and the intertwined underground horizontal roots of *Avicennia* physically support the trees in what is often a relatively unstable and shifting soil. Aerial roots and pneumatophores provide attachment sites for epibionts and facilitate the accretion of sediment by impeding water movement.

Reproduction

Many mangrove species show some form of vivipary. *Rhizophora* is an example. The ovum is fertilized while still on the

Table 1 Distribution of mangrove species by family and genus^a

parent tree and grows by a combination of photosynthesis and acquisition of nutrients from the parent until it may reach a length of 50 cm (**Figure 4**). This structure – neither a seed nor a fruit, and hence usually termed a propagule – then falls to the ground. The propagules of some species root almost immediately, but others appear to have an obligatory floating period before they sink and establish themselves. The majority of floating propagules probably settle close to the parent, but long-distance dispersal is also possible. Floating mangrove propagules may remain viable for a month or longer: Depending on current speed and direction, they could travel a considerable distance. It is not uncommon for mangrove seedlings from Mexico, for instance, to be stranded and take root in Texas virtually across the length of the Gulf of Mexico. An even greater dispersal may explain the mangrove species *Rhizophora samoensis*, which is found only in Samoa and

adjacent islands, at the opposite extremity of the Pacific from its presumed ancestor, the species *Rhizophora mangle* of Central America. The significance of dispersal ability for the geographical distribution of mangrove species is discussed in section Regional Patterns of Diversity.

Mangrove Animals: Fauna of Terrestrial Origin

Although mangrove roots are periodically immersed, the branches and leaves provide an environment little different from that in adjacent terrestrial forests, with which they consequently share much of their fauna. Mangrove animals of terrestrial, rather than marine, origin include arthropods (particularly insects, but also spiders and myriapods),

Figure 2 Aerial roots of *Rhizophora* in a Malaysian mangrove forest.

Figure 4 Mangrove propagules on a *Rhizophora* tree, Indus Delta, Pakistan.

Figure 3 Mangroves (*Avicennia marina*) on the Red Sea coast of the Sinai Peninsula, Egypt, showing dense pneumatophores.

amphibians, reptiles, birds, and mammals. Virtually none are found exclusively in mangroves.

Insects

Anyone who has worked in mangroves can testify to the abundance of biting insects, particularly mosquitoes and “sand flies” or biting midges (*Ceratopogonidae*). Mosquito larvae develop in rot holes in mangrove trees, in semi-permanent brackish pools, or in the water retained in crab burrows. In the latter case, one East African species, *Aedes pembraensis*, ensures a suitable burrow environment for its larvae by laying its eggs directly onto the claws of the crab *Sesarma meinerti*. Prey of adult mosquitoes includes, apart from humans, a variety of mangrove mammals and birds, and in some cases it extends to fish.

Ants are often abundant in mangroves, including the aggressive nest-building weaver ants (*Oecophylla*) of the Indo-Pacific and leaf-cutter ants (*Atta*) of South America. Particularly complex relationships have evolved between ants, epiphytic “ant-house” plants, and mangrove trees (Figure 5). Ant-house plants have bulbous stems (which may weigh several kilograms) honeycombed with passages inhabited by ants. One such plant, *Hydnophytum formicarium*, has specialized chambers in which ants deposit the remains of their prey, and from which the plant can absorb nutrients released by fungal action. The situation is further complicated by the presence of butterfly larvae (*Hypochrysops*) which feed on the ant-house plant and which are tended by the ants. The relationship therefore involves interactions between two plant species, two animal species, and one or more fungus.

Most mangrove ants are arboreal and essentially terrestrial animals. In many cases they nest outside the intertidal zone and forage in the mangal only at low tide. One Australian species, *Polyrhachis sokolova*, is truly intertidal, retreating at high tide to nests within the mangrove mud. Nothing is actually known of its physiology: like other intertidal insects, it may retain a surface film of air and therefore avoid the need

for any special adaptations to immersion or varying salinity. It does have some ability to swim.

Probably of greater ecological significance are the various plant-eating insects. Termites play a major role in disposing of dead wood. Some species construct nests of mud on tree trunks several meters above high-tide level, with access galleries snaking down the trunk to the aerial roots and upward to the canopy.

The most important herbivores are those that eat mangrove leaves and seedlings, particularly the larvae of moths and beetles. Typically, only a small proportion of leaf production falls to herbivory. Sometimes, however, it reaches epidemic proportions. Individual trees in an otherwise healthy forest may be completely defoliated, and occasionally areas of many hectares are stripped of leaves. Canopy loss may result in the defoliated trees dying and being replaced by other species that are more tolerant of unshaded conditions. Insect herbivory therefore may alter mangrove community structure.

Other mangrove insects include the spectacular synchronously flashing fireflies of Malaysia (*Pteroptyx*), which occupy the mangrove *Sonneratia* for their displays, and numerous species of butterfly and moth. Hawkmoths, bees, and drosophilid flies are among the species which are probably of importance in pollinating mangrove flowers.

Amphibia and Reptiles

Amphibia are rare in brackish or salt water, but one species, the crab-eating frog (*Rana cancrivora*), is common in mangrove habitats of Southeast Asia. Tadpoles survive well in salinity up to 50% that of seawater.

Reptiles are more abundant. Numerous species of snake forage within the mangal at low tide, including terrestrial or arboreal species but also some for which the mangal is their primary habitat. Mangrove snakes eat crabs (sometimes reciprocated), insects, and fish. In Southeast Asia, one of the most formidable mangrove predators is the monitor lizard (*Varanus indicus*), which may reach 1 m in length. Crocodiles, caimans, and alligators also occur in mangroves, although these are now rare in many areas due to human activities.

Figure 5 The “ant-house plant” *Myrmecodia*, epiphytic on a mangrove branch.

Birds

Birds are highly mobile. Many spend only part of their time in mangroves, migrating seasonally, daily, or tidally. Mangroves provide a feeding area, a nesting site, a refuge from the rising tide, or some combination of these. Waders probe for invertebrates in the mud of the mangal or adjacent mudflats. Kingfishers, egrets, and herons catch fish or invertebrates in the shallow water of mangrove creeks. Larger fish eaters, such as pelicans, ospreys, and cormorants, range further afield and may return to the mangal to roost or breed. In the Caribbean, roosts and nesting colonies of cattle egrets (*Bubulcus ibis*) and scarlet ibis (*Eudocinus ruber*) are so densely packed that the consequent enrichment of the soil with guano leads to significantly enhanced local growth of the mangrove trees.

Mangrove forests typically include numerous passerine species. Nectar feeders such as sunbirds in Malaysia, honey-eaters in Australia, and hummingbirds in South America move

seasonally into mangroves and may be important pollinators. Insectivorous passerines specialize in hawking for insects in the canopy or, among low-lying vegetation, in picking insects off leaves or from bark crevices or from different species of tree. Broadly similar guilds of insectivorous birds, comprising different constituent species, seem to occur in different geographical regions.

Few of the species found within the mangal are mangrove specialists, and those which are restricted to mangroves in one part of the world may occupy different habitats elsewhere. One example is the cosmopolitan Great tit (*Parus major*), distributed from western Europe to China: only in Malaysia is it a mangrove species. The lack of mangrove specialists is probably due to the relative simplicity of the mangrove forest structure compared with typical tropical forest, allowing less scope for niche specialization. Another reason is probably the proximity of a pool of competing species in adjacent tropical rain forest. There are proportionally fewer mangrove specialists in New Guinea, where rain forest usually abuts mangrove habitats, than in Australia, where this juxtaposition is less common. Within Australia, there are fewer specialists in the mangroves of Queensland, which are extensive and contiguous with rain forest, than in northwestern Australia, where this is not the case. Most mangrove birds are probably using the habitat opportunistically.

Mammals

As with birds, many mammal species use the mangal opportunistically. These include small rodents, agoutis, wild pigs, antelopes, deer, and rhinoceroses; the Sundarbans of Bengal are the last major redoubt of the Bengal tiger (*Panthera tigris*). Domestic animals, such as camels and buffalo, are often a major element in the mangrove fauna. Otters may also be abundant, feeding on fish and crabs from the mangrove creeks.

Monkeys are common in mangroves. In Southeast Asia these include macaques (*Macaca*) which forage on the mud for crabs and mollusks. They also uproot large numbers of mangrove seedlings: Because these are seldom eaten or even greatly damaged, the purpose is not clear. Herbivorous monkeys are found in the forest canopy, including leaf monkeys (*Presbytis*) and, in the mangrove forests of Sarawak, the striking proboscis monkey (*Nasalis larvatus*). This is found only in mangroves and riverine forests, and it specializes in eating foliage, which is digested in an elaborate multichambered stomach with the aid of resident bacteria.

Bats are often abundant in mangroves. Resource partitioning in insectivorous bats parallels that of insectivorous birds, with species specializing in different zones of the mangrove vegetation and catching their prey with different flight techniques. A single bat may eat up to one-third of its body weight of insects each night: a 30-g bat might therefore consume 5000 insects nightly. The impact on the insect population of foraging bats must be considerable.

The exclusively Old World fruit bats often occur in mangrove forests in vast numbers: Roosts of an estimated 220,000 individuals have been recorded. Most fruit bats feed on nectar and fruit, and it is this which attracts many species into the mangal. In Malaysia, the long-tongued fruit bat *Macroglossus minimus*

is an important pollinator of the mangrove *Sonneratia*: the long tongue is specialized for insertion into the *Sonneratia* flower, which carries large projecting stamens to deposit pollen onto the fur of the feeding bat. *Sonneratia* flowers last for only a single night, possibly because of the wear and tear resulting from visits by such a large pollinator. This species of bat is a true mangrove specialist, and in western Malaysia at least, it has not been recorded from other habitats. Mangrove specialization is possible only because the three species of *Sonneratia* in the area have different flowering patterns so that nectar is available throughout the year. Other fruit bats switch seasonally between mangrove and nonmangrove species.

Fauna of Marine Origin

One of the principal reasons for the high faunal diversity of mangrove ecosystems is their accessibility to occupation by organisms from both terrestrial and marine habitats. Of these, the marine invaders are the more numerous in terms of numbers and diversity of species. These include more or less sessile organisms settling on aerial roots and pneumatophores as well as more mobile species living on and under the mud. Many animal groups are represented in the mangal, the most conspicuous and ecologically most significant being teleost fish, crustacea, and mollusks. As with the land-derived mangrove fauna, the majority of species occur elsewhere and accumulate in mangroves because of the availability of food, shelter, or suitable substrate.

Considering mangrove communities at a scale of, for example, hectares, the diversity of such animals is often high. At smaller scale, however, the anoxic conditions caused by waterlogging, exacerbated by microbial decomposition of detritus, may greatly reduce both species diversity and abundance.

Root Communities

Mangrove roots and pneumatophores provide a hard substrate often covered with a rich and diverse growth of sponges, sea anemones, bryozoans, tunicates, barnacles, tubeworms, and mollusks as well as epiphytic algae. These in turn may attract a more mobile population of browsers or predators. The epibionts are mostly filter feeders, extracting organic particles suspended in the water, or predators of zooplankton, with no direct interaction with their mangrove host. A particularly thick growth, however, can adversely affect the host tree by occluding lenticels and restricting gas exchange with the underground roots. The relationship is sometimes mutually beneficial, as encrusting sponges may transfer nitrogenous nutrients to their host, and encrusting fauna can protect the root from attack by wood borers.

The labyrinthine aerenchyma tissue of the roots is easily penetrated by wood-burrowing organisms. The isopod crustacean *Sphaeroma* is a common root borer and may cause severe damage and even death. *Sphaeroma*-induced damage near the growing tip of a root may induce forking, with a resulting increase in the number of roots entering the soil: This may benefit the tree. The "shipworm" *Teredo* (which is in fact a mollusk)

also bores dead roots and trunks extensively and plays a similar role to that of termites in disposing of woody debris. Like termites, *Teredo* relies on symbiotic microorganisms to digest the more intransigent components of wood.

Fish

Mangrove creeks and inlets are frequently occupied by abundant and diverse fish populations. In Southeast Asia, for instance, records of more than 100 species are by no means unusual. Many of these species spend only part of their time within the mangal, often moving to other habitats seasonally or at different stages of their life cycle. Mulletts (*Liza*) eat significant amounts of mangrove detritus, such as shed leaves: most hunt small Crustacea or other invertebrates. Some fish are permanent creek residents, commuting into the forest when it is submerged at high tide and foraging among the mangrove roots.

At low tide, Asian mangroves are occupied by mudskippers, which are relatives of the gobies (Figure 6). As their name suggests, they skip across the exposed mud surface using their tails and leg-like pectoral fins, sometimes even climbing up aerial roots or pneumatophores. This amphibious life requires appropriate physiological adaptations, particularly in relation to respiration. Mudskippers are largely air-breathing, with gas exchange taking place not just across the gills but also at highly vascularized areas of the skin. Some store air within their burrows to enable aerial respiration even at high tide.

All mudskippers are probably to some extent omnivorous, but some are predominantly deposit feeders and others carnivores. Prey of the latter include crabs, insects, spiders, shrimps, and snails.

Crustacea

Mangrove habitats, particularly in the Indo-West Pacific, are dominated by crabs belonging to two families, Grapsidae and

Ocypodidae. The former are predominantly herbivores or detritus feeders and the latter deposit feeders, extracting fine organic particles from mangrove mud. Predatory crabs, such as the formidable *Scylla*, may also be important components of the mangrove fauna. Shrimps (Penaeoidea) and mud lobsters (*Thalassina anomala*), and smaller Crustacea such as amphipods and isopods, may also be significant as scavengers, in breaking down leaf litter, or as predators of smaller organisms.

Grapsid Crabs

Grapsid crabs of the subfamily Sesarinae, particularly of the genus *Sesarma*, are characteristic of mangroves, although a few species of this genus occur in other habitats (Figure 7). More than 40 species of sesarmine have been reported from the mangroves of Malaysia alone, and many species, here and in other regions, undoubtedly remain to be described.

Figure 7 Mangrove sesarmine crabs: (a) *Parasesarma plicata*, (b) *Aratus pisonii*, and (c) *Neosarmatium smithi*. Reprinted from Jones DA (1984) Crabs of the mangal ecosystem. In: Por FD and Dor I (eds.) *Hydrobiology of the Mangal*, pp. 89–109, with permissions from Kluwer Academic Publishers and the author.

Figure 6 Mudskipper on an *Avicennia* pneumatophore.

Sesarma are small (usually less than 3 cm in breadth) and inconspicuously colored. They are amphibious, retreating into burrows at high tide and foraging on the exposed mud at low tide. Respiration in air is achieved partly by recirculating water from the gill chambers over the carapace where it can be reoxygenated: evaporative cooling during this process also serves to reduce the dangers of high air temperature. Water loss can be offset by the acquisition of soil water through tufts of root-like hairs. Sesarmines are euryhaline, although differing degrees of salt tolerance probably contribute to the zonation of crab species along estuaries or with shore level.

In some cases, sesarmine crabs climb trees to feed on fresh leaves or buds. In East Africa, *Sesarma leptosoma* undertakes synchronized mass migrations twice daily from refuges among mangrove roots to forage on the tips of the branches of the trees. The virtually indistinguishable Caribbean species *Aratus pisonii* spends most of its time in trees, only rarely descending onto the mud.

Most sesarmines, however, subsist on fallen leaves or propagules. Mangrove leaves are often rich in tannins and other aversive materials, and several crab species have been shown to select leaves from the more palatable species of tree. Many leaves are collected as soon as they fall and cached in crab burrows. As decomposition proceeds, tannin levels decrease and nitrogen content increases through the accumulation of microbial biomass: storage therefore increases leaf palatability.

Much of the leaf material eaten is not assimilated but redeposited onto the mud as feces, available for microbial decomposition. It has been estimated that processing of leaf material by crabs increases the rate of breakdown of leaf litter 75-fold compared with the rate of decomposition under microbial action alone. Therefore, sesarmine crabs collectively play a very important role in facilitating energy flow through the mangrove ecosystem. By eating propagules, they also affect species distribution and community structure of mangrove trees (see Tree Distribution). However, there are geographical differences: in Southeast Asia and Australia, sesarmines are crucial in litter breakdown and selective removal of propagules, whereas in Florida and the Caribbean they are of lesser significance.

Ocypodid Crabs

Some crabs of the family Ocypodidae, such as the Central American hairy land crab *Ucides*, consume mangrove detritus. The majority are deposit feeders. Among these, the most conspicuous are the gaudily colored fiddler crabs (*Uca* spp.), widespread throughout the mangroves of the Old and New World (Figure 8).

The common name derives from the one greatly enlarged claw of male fiddlers, which is used in courtship and in deterring rival males. The smaller claw of males and both claws of females are devoted to feeding. Mud is scraped into the buccal cavity in which, by a complicated process of flotation and manipulation by the mouthparts, fine organic particles are separated from the mineral components. The former is ingested and the latter deposited as a ball of sand, or "pseudofecal pellet." The process of separation may be quite selective. In some species, what is extracted consists almost entirely of microbial cells rather than, for example, frag-

Figure 8 Fiddler crab (*Uca*) in a Mozambique mangrove (photograph courtesy of D. Barnes).

mented leaf material. Others have subtly different extraction techniques and may specialize in the smaller meiofaunal animals. There may be as many as 60 fiddler crabs per square meter, resulting in 500 g of soil being processed daily. The toll on meiofauna is probably considerable, and the effects on soil texture and composition are profound.

Other Mangrove Crustacea

Other crabs found in mangroves are important predators. The most conspicuous is the mud crab *Scylla serrata* of the family of swimming crabs (Portunidae). *Scylla* reaches a carapace width of up to 20 cm, making it the largest invertebrate predator found in mangroves. Equally formidable predators are the mantis shrimps (Stomatopoda), which live in burrows in the mud and lacerate prey by rapidly shooting out their viciously spiked raptorial appendages. Other rarely seen burrowing crustaceans include pistol or snapping shrimps (*Alpheus* spp.) and the mud lobster *Thalassina* (see Crustacea as Ecosystem Engineers).

More general mangrove scavengers include hermit crabs, particularly *Clibanarius*, which forage on the mud surface at high tide. Shrimps may also be abundant in mangroves and mangrove creeks. Penaeid shrimps, which in at least some parts of the world depend heavily on mangroves for feeding and breeding, are an important commercial crop. The shrimp *Merguia* apparently lives only in mangroves and has the distinction of being the only semiterrestrial shrimp: it actually climbs trees. Only two species are known. One occurs in the Indo-West Pacific region, from Kenya to Indonesia, and the other occurs in Panama, Brazil, and Nigeria. Indo-West Pacific and Atlantic regions differ in the composition of their mangrove floras, and the separation of the two species of mangrove-associated shrimps may have occurred in parallel with the divergence of the mangroves themselves.

Crustacea as Ecosystem Engineers

All species have an impact on their environment, at the very least exchanging materials in the form of food, waste

materials, and respiratory gases. Some species have effects beyond these simple transactions and alter the nature of their environment in ways that affect species other than their direct competitors, predators, or prey. Such species are often termed "ecosystem engineers."

In a mangrove ecosystem, the trees are the greatest engineers, influencing sedimentation rates and creating a physical environment. Crustacea also, in important ways, transform their surroundings. The topography of mangrove swamps in Southeast Asia is often visibly modified by mud lobsters (see section Other Mangrove Crustacea). While processing mud, *Thalassina* throws up waste material from beneath the surface, forming mounds which may reach 2 m in height. These create patches of dry mud which provide habitats for other species, including the mangrove fern *Acrostichum*, fiddler crabs, and a variety of other burrowing Crustacea and mollusks. Between the mounds the mud surface is lower, and more waterlogged, than it would be otherwise. Burrowing crabs also contour their environment, although less dramatically.

Much of the microbial activity of mangrove mud occurs in the surface layer, to a depth limited by the diffusion and exchange of gases with the atmosphere. As fiddler crabs process surface mud, they continually expose fresh material, facilitating microbial activity, while the active surface of the mud is increased in area by crab burrows. Burrowing activity also oxygenates the deeper soil and creates an underground labyrinth of interconnecting passages, through which significant underground water flow occurs. Experimental evidence suggests that crab activities significantly affect nutrient recycling and enhance growth of mangrove trees. Crustacea therefore alter the state of their environment in ways that significantly affect other species.

Mollusks

Bivalves

The most visible bivalve mollusks of mangroves are the oysters and mussels found attached to roots. Within the mud, however, there is often an abundant population of burrowing species. These, like the oysters and mussels, are largely filter feeders, extracting fine organic particles from suspension. A less typical group of bivalves are the shipworms of the family Teredinidae (see Root Communities), including the giant mangrove shipworm *Dicathifer*, which may reach 2 m in length.

Snails

Gastropod snails are also generally abundant in mangroves. As with the crustacean fauna, these include herbivores, detritus and deposit feeders, and predators. Although a few species are uniquely found in mangroves, the majority of surface-living species also occur on open mudflats.

The principal predatory snails are species of *Thais*, found in mangroves worldwide. These cruise over mud and mangrove roots, feeding on barnacles or smaller gastropods. In the mangroves of Costa Rica, for example, *Thais kiosquiformis* densities may reach more than 200 per square meter, and the species plays a major role in maintaining the function of mangroves by removing encrusting fauna from their roots.

Many gastropod species are deposit feeders, ranging in size from tiny and almost invisible species to the massive *Terebralia* and *Telescopium* of the Indo-Pacific region, which may reach a length of 10 cm (Figure 9). One species, *Terebralia palustris*, feeds on small detritus particles when young, but on reaching a length of approximately 3 cm it switches to a diet of fallen leaves. The teeth on the radula (the ribbon-like tongue) of gastropods metamorphose appropriately to a form suitable for the altered diet. In Florida, snails are important consumers of mangrove seedlings, at some locations destroying nearly three-fourths of the seedling population. This is an interesting geographical contrast with other regions, such as Malaysia and Australia, where crabs fulfil this role (see Grapsid Crabs).

The most abundant snails on the mangrove trees are often species of *Littoraria*, close relatives of the periwinkles of temperate rocky shores. In Central America, on both sides of the Isthmus of Panama, the common species is *Littoraria angulifera*. In the Indo-Pacific, this species is replaced by many others, which partition between them the slightly different habitats afforded by a tree. In Papua New Guinea, *Littoraria scabra* prefers the bark of trees on the seaward side of a forest,

Figure 9 Gastropod mollusks typical of Indo-West Pacific mangroves: (a) *Pythia* (2.5 cm), (b) *Telescopium* (10 cm), (c) *Terebralia* (6 cm), and (d) *Cerithidea* (2 cm). Reprinted from *Advances in Marine Biology* 6, Macnae W, A general account of the fauna and flora of mangrove swamps and forests in the Indo-West Pacific Region, 74–270, 1968, with permission from Academic Press.

Littoraria intermedia prefers trees next to freshwater creeks, whereas the polymorphic species *Littoraria pallescens* is found solely on leaves.

Meiofauna

Within the mangrove mud lies a rich fauna virtually invisible to the naked eye – the meiofauna. Beneath an area of 10 cm² of mud there may be many thousands of individuals. Orders of magnitude smaller than the more conspicuous macrofaunal crabs and snails are meiofaunal herbivores, detritivores, and formidable predators, with food chains probably dependent on photosynthetic cyanobacteria (“blue-green algae”) and heterotrophic bacteria. Meiofauna colonize fallen leaves, and the stages of leaf breakdown are accompanied by complex interactions and successional shifts in species composition and community structure which parallel, on a microscopic scale, the processes of macroecology.

The numbers of meiofaunal individuals are immense, and their diversity is astonishingly high. Not only are there many species but also the species show a higher level of taxonomic diversity. Among the macrofauna virtually all species belong to just three phyla: arthropods, mollusks, and chordates. The meiofauna from just one mangrove area in Australia, for example, yields turbellarian flatworms, nematodes, copepods, Ciliophora, Foraminifera, bivalve mollusks, oligochaete and polychaete annelids, hydrozoa, archiannelids, kinorhynchans, tardigrades, and gastrotrichs.

Very little is understood about the meiofauna of mangroves, their interactions, their functional significance in the ecosystem as a whole, and the relationship between the meiofaunal and macrofaunal worlds. Their small size belies their great importance.

Connections

The salient features of typical mangrove ecosystems are relatively high rates of primary productivity, much of the results of which enter decomposition pathways, either directly or after initial breakdown by leaf-eating crabs or mollusks. This is true of leaves and reproductive structures and, on a more protracted timescale, of the woody components of the trees. Particulate organic matter, either small leaf fragments or bacterial cells, is ingested by molluscan and crustacean deposit and filter feeders, enters meiofaunal food chains, or accumulates in the mud.

The ecosystem can be viewed physically as well as in terms of the flow of energy or matter. Mangrove trees supply hard surfaces on which other organisms settle, and they modify (as well as respond to) the physical environment by stabilizing the soil, facilitating accretion of mud, and retarding erosion. The environment is further modified by the physical activities of burrowing Crustacea and other animals.

Mangrove ecosystems cannot be considered in isolation. They interact with adjacent habitats through the trapping of exogenous sediment or export of particulate or soluble organic matter or inorganic nutrients. Animals, by moving between mangroves and other habitats, also contribute to import

and export of matter. Commercially important penaeid shrimps use mangroves as nursery areas so that shrimp catches many miles away may depend critically on mangrove productivity. Hard evidence for such connections between mangroves and other ecosystems, however, is sometimes elusive, and the strength of such linkages is almost impossible to quantify.

Mangrove diversity

Mangrove diversity must be considered at a range of spatial scales, from global patterns of species richness to the pattern of distribution, at a particular location, at a scale of a few meters. In considering mangrove fauna, even smaller spatial scales become relevant. At all scales, diversity is affected by the past history of the area, by physical factors, and by biotic interactions, but the importance of each of these and the timescales over which they operate vary with scale (Duke *et al.*, 1998).

Global Patterns

Latitudinal Range and Species Diversity

Mangroves are almost exclusively tropical or subtropical. This distribution is a reflection of a temperature limitation: The global distribution of mangroves correlates very closely with, for example, the winter position of the 20 °C isotherm (Figure 10). The number of mangrove species declines with increasing latitude, with the most northerly and southerly mangroves being species of *Avicennia*. In temperate regions, mangroves are replaced by salt marsh vegetation: plants which, like mangroves, are adapted to conditions of salinity and waterlogging but which do not carry the additional burden of being a tree or of producing large propagules.

Longitudinal Differences

Within their temperature and latitudinal constraints, mangroves show interesting patterns of species distribution. The principal biogeographic division is between the Indo-West Pacific (IWP) and Atlantic–Caribbean–east Pacific (ACEP) regions. These two regions have broadly similar areas of mangrove habitat, but the IWP has four times more genera and six times as many species of mangrove: 17 genera compared to 4, and 40 species compared to 7. It is apparent that none of the mangrove genera are very diverse, possibly because of a general limitation on species diversification in harsh intertidal conditions. Genera occurring in the IWP, however, are slightly more speciose than those of the ACEP: 2.35 compared with 1.75 species per genus.

The differences between the IWP and ACEP regions are maintained by major barriers. The most obvious of these is the African continent (Figure 10). Less obvious is the barrier represented by the central Pacific. This results principally from dispersal limitations rather than from the absence of suitable habitat. Suitable environments are present on many Pacific islands without natural mangrove populations, as shown by the success of the artificial introduction of mangrove species to Hawaii.

Figure 10 World distribution of mangroves in relation to 20 °C isotherms. Reprinted from Duke NC (1992) *Mangrove floristics and biogeography*. In: Robertson AI and Alongi DM (eds.) *Tropical Mangrove Ecosystems*, pp. 63–100, with permission from American Geophysical Union and the author.

Figure 11 Comparison of the mangrove flora in six geographical subregions. Because of the recent closure of the Isthmus of Panama, the eastern Pacific and western Atlantic (including Caribbean) are most similar in species composition. Note also the separation between Atlantic–Caribbean–eastern Pacific (ACEP) and Indo–West Pacific (IWP) regions.

Further dispersal barriers, including the Isthmus of Panama, open ocean, and arid coasts unsuitable for mangrove occupation, divide the major regions into smaller subregions, each with a more or less distinctive mangrove flora (Figure 11). Only one species occurs in all six subregions: the mangrove fern *Acrostichum aureum*. Two genera, *Avicennia* and *Rhizophora*, are common to both IWP and ACEP regions. All other genera are found exclusively in either the IWP or the ACEP, although the close similarity between *Laguncularia* (ACEP) and *Lumnitzera* (IWP) suggests a recent separation of these two genera.

The traditional explanation of mangrove species distribution is of a center of origin and of diversification in

Southeast Asia, followed by dispersal restricted by physical barriers. This clearly makes little sense in relation to the current dispersal barriers. Fossil evidence of mangroves is widespread and reveals a much wider distribution during the Eocene and earlier epochs: Fossil *Nypa*, *Avicennia*, and *Rhizophora* pollen and other remains, for instance, have been identified in Eocene and Miocene deposits that now form part of North and South America, Europe, and North Africa as well as south and east Asia. At the time, these locations were connected by the Tethys Sea, continuous through what is now the Mediterranean and Indian Ocean.

Subsequently, this pantropical distribution was partitioned as a consequence of continental movements. Cosmopolitan genera such as *Avicennia* and *Rhizophora* were separated into regional populations by the approach of Africa to Asia 30–35 million years ago which closed the Tethys Sea, and separation of the sister genera *Laguncularia* and *Lumnitzera* followed the widening of the Atlantic barrier. The emergence of modern species ensued within the isolated subregions. Closure of the Isthmus of Panama was geologically very recent (a mere 2 or 3 million years ago) so that differences between eastern Pacific and Caribbean species are slight. One species (*Pelliciera rhizophorae*) is found on both sides of the Isthmus, presumably reflecting a separation into two populations too recently for allopatric speciation to have occurred.

An originally pantropical mangrove distribution was therefore partitioned into regions and subregions, with subsequent evolutionary divergence. Climatic conditions then eliminated mangrove species from areas such as southern Europe and the Mediterranean fringes. The current distribution pattern results from a combination of large-scale geographical factors and more regional climatic ones.

Diversity of Mangrove Fauna

It might be expected that faunal species diversity would follow a similar pattern to that of mangrove tree diversity both because the mangrove fauna has presumably been exposed to the same influences and because of a presumption that faunal diversity should respond to tree diversity.

The IWP region, richer in plant diversity than the ACEP, is also richer in species of mangrove-associated Crustacea and mollusks (Table 3). The reverse is true of other taxonomic groups, particularly those that form constituents of the root communities, such as sponges, coelenterates, and echinoderms. This may reflect regional differences in tidal range and availability of roots for settlement. For many groups, unfortunately, little comparable data are available and recorded species numbers reflect taxonomic interest and effort rather than the composition of actual species assemblages.

Regional Patterns of Diversity

Species diversity varies within regions in response to many different factors. The ACEP region, in addition to having fewer mangrove species in total, shows less differentiation between localities within the region, and all the species available in the geographical vicinity are likely to be represented at most locations.

Various factors may result in local variation in species diversity. Mangroves do not grow on rocky shores or in areas where fresh water is completely lacking (which is in part why all tropical shores are not dominated by mangroves). Stretches of inhospitable coastline therefore act as barriers which affect mangrove dispersal and geographical distribution. The arid shores of Somalia, for example, result in the reduction in species number northwards so that *Avicennia marina* is virtually the only mangrove species found in the Red Sea. Separation of mangrove estuaries from each other by arid coastline, and regional-scale variation in physical variables, also affects the species distribution of mangroves around the Australian coasts.

Dispersal ability also affects species distributions within regions. The number of mangrove species on islands of the western Pacific shows clear attenuation with increasing distance from the species-rich areas of Australia and Papua New

Guinea. Similarly, among islands off the West African coast there is a clear relationship between the number of mangrove species present and the distance from the nearest landward neighbor (Figure 12). Species number also correlates with island size, with larger islands containing more species.

Local Variation in Species Distribution and Diversity

Tree Distribution

At a specific location, the distribution of mangrove species responds to physical variables in the environment. These often vary as gradients: in an estuarine mangal, for instance, salinity and the influence of tidal fluctuations tend to diminish with distance up the river. Sediment composition and nutrient dynamics also alter with distance from the open sea. Mangrove species respond differentially to such upriver/downriver gradients, resulting in zonation of species.

Similarly, in areas dominated by tide rather than river flow, tidal fluctuations establish gradients of physical variables, particularly in salinity and the extent of waterlogging of the soil. Again, mangrove species respond differentially to these physical variables and tend to form distinct zones. Where both river and tidal influences interact, the pattern of species distribution can be extremely complex.

In relation to salinity, species generally grow better at low salinity and differ more in the tolerance range than in their salinity optima. Low salinity, in consequence, tends to be associated with higher species diversity. At higher salinities, tolerance differences result in differing competitive success and translate into zonation of mangrove species along a salinity gradient, with species dominating zones at which they compete best, rather than those corresponding to salinity growth optima.

Although response to physical gradients suggests a gradual transition from one species to another as the determining physical variable gradually alters, this is often not the case. Mangrove species are frequently found in virtually monospecific stands or zones, with a more or less abrupt transition from one dominant species to another. This suggests that interactions between tree species, and mutual exclusion, may play a part in defining zone boundaries. Other physical

Table 3 Number of species recorded from mangroves in various localities in the regions indicated

Figure 12 The number of species of mangrove occurring on West African islands in relation to their distance from the nearest landward neighbor.

variables, such as the degree of waterlogging and soil anoxia, nutrient availability, and biotic interactions between species, similarly affect species distribution within the mangal.

Superimposed on the sorting of species under the influence of physical variables are variations resulting from interactions with the mangrove fauna. Of the faunal influences, the most significant is the selective destruction of mangrove propagules by sesarmine crabs (see section Grapsid Crabs). At least in Southeast Asia and Australia, this is a major factor determining mangrove species distribution. Mangrove animals respond to physical gradients of salinity and inundation regime. Sesarmine abundance is often greatest at midshore, and it is therefore here that mangrove propagules are most vulnerable. For reasons related to nutritional value and the levels of aversive tannins, *Avicennia* is generally the preferred food of sesarmines: hence at some locations the distribution of *Avicennia* in the upper and lower shore and their virtual absence from intermediate shore levels.

Random factors can also affect mangrove species distributions. If a gap is created in a mangrove forest because of the death of a tree, it is most rapidly filled by the species that are the best colonizers and best able to flourish in unshaded conditions. In Southeast Asia, the result is often an initial invasion of the mangrove fern *Acrostichum*. This may be succeeded by seedlings of *Bruguiera parviflora*. This species has relatively small and easily dispersed seedlings, whose growth is suppressed by the shade of an intact canopy. These in turn are replaced by slower growing shade-tolerant species such as *Bruguiera gymnorrhiza*. *Avicennia marina* is less tolerant of shade but is less likely to occupy a small gap because of propagule destruction by crabs. If, however, the gap is a large one, *Avicennia* is more likely to establish itself, probably because foraging crabs are vulnerable to predation in large open spaces. The distribution of species within a mangrove forest may therefore be patchy and reflect the stochastic nature of tree death and the subsequent successional history. On a larger scale, extensive death of trees by typhoons, by widespread defoliation by insect attack, or even by oil spills can have profound and long-lasting effects on species composition.

The structure of a mangrove forest is therefore in part explainable in terms of "patch dynamics" – of gaps appearing by

chance and being filled by a changing assemblage of species differing in composition (at least for a time) from the surrounding forest. Eventually, something similar to the surrounding forest emerges. With a high incidence of gaps, a mangrove forest could be seen as a mosaic of patches of different successional age: if patches appear relatively rarely, the effect would be transient aberrations in an otherwise homogeneous, or consistently zoned, environment.

Distribution of Mangrove Animals

The species distribution of the mangrove fauna is less well understood since small, cryptic, and often mobile animal species are less easy to describe and analyze than large and immobile trees. A high level of taxonomic confusion compounds the problem. Nevertheless, it seems likely that the same general considerations apply. The distribution of mangrove crabs, for instance, forms zones related to shore level, salinity, and soil texture, whereas mollusks show zonation patterns in relation to shore level and to vertical position on the roots and trunks of mangrove trees.

The distribution of species of mangrove animals may also be related to patch size and the distance between neighboring patches, on a smaller spatial scale than applies to the distribution of mangrove species themselves, corresponding to the more limited dispersal ability of the species in question. This was demonstrated in the classical experiments of Simberloff on the terrestrial arthropod fauna (principally insects) of mangrove islets in the Caribbean. The species richness on a range of mangrove islets increased with the area of the islets and decreased with increasing distance from potential sources of fresh colonists. When the fauna of islets was completely eliminated with pesticides, recolonization soon established an equilibrium species richness similar to that before the elimination. In terms of the representation of different functional groups the previous situation was largely replicated, but the actual species comprising the new assemblages differed. Finally, artificially reducing the area of mangrove in experimental islets reduced species richness, showing that it was causally related to habitat area rather than to habitat diversity.

At an even smaller scale, individual mangrove roots can be regarded as “islands” of habitat suitable for epibiont settlement, surrounded by areas of unsuitable habitat. Here, too, the composition of root epibiont communities appears relatively stable in terms of functional groups. The actual species present are much more unpredictable and particularly affected by physical variables and by the supply of colonizing larvae. These factors are of different significance at different time and spatial scales.

Meiofaunal diversity has scarcely been investigated, although the same considerations apply as in the macrofaunal world. Variation in physical variables, species interactions, patchiness, dispersal, and the other factors relevant to larger organisms must also affect the meiofauna. To date, limited research interest (and the intrinsic difficulty of studying species interactions or measuring, e.g., nutrient gradients at a scale of millimeters) has restricted our knowledge of mangrove meiofaunal diversity and the factors which determine it.

Genetic Diversity of Mangroves

The advent of molecular genetic techniques has made it possible to study diversity at levels lower than the species. To date, few species have been studied, and clear general conclusions cannot be drawn. In some cases, such as the self-pollinating *R. mangle* of Florida and the Caribbean, populations appear to be genetically homogeneous, with slightly more genetic variation toward the northern extremes of the species' range. The extent of intraspecific genetic variation varies with the breeding structure of the population, with dioecious species showing much greater polymorphism. Genetic variation between populations is naturally greater than that within a population at a particular location, although West African mangroves have greater levels of genetic diversity than the same species in the Florida and Caribbean. This confirms the belief that western Atlantic mangroves derive from African populations rather than the reverse. As research proceeds, no doubt many such insights into the causes and consequences of intraspecific diversity will emerge.

Uses and Abuses of Mangroves

Mangroves are of interest not just to biologists. Their diversity and productivity makes them the source, directly and indirectly, of many products of use (and commercial importance) to humans (Bandaranayake, 1998).

Mangrove trees are exploited for timber for construction and firewood. This ranges from the casual collection of fallen wood to major charcoal industries based on the intensively managed mangroves of, for example, western peninsular Malaysia. Foliage may also be grazed directly or harvested for fodder for domestic animals. On a smaller scale, mangrove products are collected for a host of other purposes, including thatching houses, the manufacture of fish traps, for use in medicine, for tanning leather, and for use in various foods and drinks. Indirectly, mangrove productivity supports fisheries, both within the mangal and offshore. Less tangibly, mangroves can be of considerable importance in consolidating shorelines and limiting coastal erosion.

The significance of mangroves to humans varies greatly from place to place, but attempts have been made to achieve an overall economic valuation of the goods and services

supplied. One recent estimate indicates that, on average, the annual value of a hectare of mangroves is approximately \$10,000, resulting in a worldwide total contribution of \$1,648,000,000.

An asset of this magnitude is worth conserving. Unfortunately, sustainable management of mangrove resources is the exception rather than the rule. In almost all parts of the world, mangroves are under pressure from irrigation schemes which divert rivers and prevent fresh water from reaching mangroves and from pollution, overexploitation, or deliberate clearance for construction or for the planting of alternative crops. One of the most destructive processes in many countries of Southeast Asia and Central America has been the clearance of mangroves for the construction of shrimp ponds – an attempt to increase the production of species dependent on mangroves while simultaneously reducing the primary production on which they depend. Not surprisingly, this has not been a success.

During the past few decades, loss of mangrove area in many countries has been dramatic. In the Philippines, for example, 60% of the mangrove area has disappeared, whereas in other countries such as Malaysia, Thailand, and Pakistan, annual losses are of the order of 1–3%. It may be, however, that the tide is turning. The virtual collapse of the shrimp industry in several countries and a greater awareness of the value of mangroves as a natural resource have focused attention on rational management strategies and on the possibility of reversing some of the damage. Much effort is now being put into replanting mangroves in abandoned shrimp ponds and the rehabilitation of denuded areas for coastal protection or in support of local fisheries as well as into developing suitable mangrove areas for ecotourism. The destruction of mangroves has largely been due to human activities: In the future their survival may also depend on mankind.

Glossary

Benthic Pertaining to the bottom of the sea or other aquatic environment.

Benthos Organisms living on, in, or near the seabed or at the bottom of some other aquatic environment.

Coastal Estuaries, semiencllosed seas, and shallower regions of the ocean, including areas influenced by rivers and runoff from land.

Community A group of species cooccurring in an area and interacting through trophic and spatial relationships.

Coral reef Benthic environments characterized by reef-building corals with symbiotic dinoflagellates.

Deep sea Volumes of water or areas of ocean bottom at depths greater than 200 m.

Mangrove Environments characterized by mangrove trees.

Nekton Actively swimming pelagic organisms.

Pelagic Pertaining to the water column in aquatic environments.

Plankton Organisms that float freely in the water column and do not maintain their position independent of water movements. Phytoplankton (literally plant plankton) is plankton with photosynthetic pigments and zooplankton is animals of the plankton.

Marine Ecosystems

Ecosystem Units

On land, ecosystems are separated into two-dimensional biomes, land areas defined by characteristic primary producing plants such as trees, grasses, and shrubs. Most shallow lakes and streams are similarly two dimensional; however, a few freshwater deep, ancient lakes, such as Lake Baikal in Siberia, and large rivers such as the Amazon have spatial complexity comparable to many coastal marine ecosystems. The ocean biosphere has an average depth of 4 km and comprises 99.5% of the biosphere. The dense seawater medium allows at least part of the life cycle of almost all marine organisms to be transported and dispersed by ocean currents. One ocean phylum is entirely pelagic, and about a third of the ocean phyla have representatives that spend their entire life cycle in near-surface waters as plankton. The boundaries that define ocean habitats and communities may involve a variety of overlapping criteria such as depth, distance from land, separation by landmasses, ocean currents, water masses of characteristic salinity and temperature, depth, and sea bottom characteristics such as sediment texture, composition, and surface topography. In addition, interactions with land and rivers and patterns of ocean circulation, light, nutrients, hydrology, and physical energy of water movements can strongly influence the distribution of species.

Descriptions of species boundaries are few and biogeographical classification depends heavily on the groups of organisms considered and how well they have been sampled. The ocean generally lacks the obvious barriers to dispersal characteristic of terrestrial environments. There may be multiple criteria for defining biogeographical provinces or marine ecosystems. For example, 64 large marine ecosystems (LMEs) are defined as oceanic areas of 200,000 km² or greater that extend from a coast to the margins of continental shelves or the seaward extent of predominant coastal currents (Sherman and Duda, 1999). The United Nations Environment Programme (UNEP) Regional Seas Programme has developed legally binding conventions for countries bordering 18 LMEs

to protect the marine environment. At present, Marine Protected Areas occupy 1.17% of the global ocean surface or 4.32% of continental shelf areas, well below the 10% target set by the Convention on Biological Diversity in 2004 (United Nations Environment Programme, 2010).

Vulnerable Marine Ecosystems are defined by “geographic boundaries or by types of organisms and ecological processes (e.g., seamounts, coral reefs, continental slopes, abyssal plains) and ecosystems” (FAO, 2007). Ecosystem vulnerability may depend on the sensitivity of individual species, the ecological roles of threatened species, local types of hydrothermal vent and seep habitats, deep-sea sediment transport, and unique major bottom features such as seamounts, deep canyons, and slopes of volcanoes (Snelgrove, 2010). For example, in the Southern Ocean large areas of relatively undisturbed deep-sea bottom sediments are of special interest as habitat with a high diversity of species. Near the end of the first Census of Marine Life in 2010, ANDEEP (ANtartic DEEP-sea biodiversity: colonization history and recent community patterns) had identified 1400 species of invertebrates and more than 700 species appear to be new to science. Of the 674 species of isopods, 87% are believed to be newly discovered species (Ramirez-Llodra *et al.*, 2010). To date, the Ocean Biogeographic Information System (OBIS), a legacy of the Census of Marine Life, has 30 million records of 118,000 species in 31,000 genera (<http://www.iobis.org/node/299>).

Major estuaries, where freshwater from rivers mixes with ocean water, are among the smallest individual ecosystem units in area. The largest units are regions defined by major boundary currents: features such as the Gulf Stream, Kuroshio, and Brazil currents, and the north and south subtropical ocean gyres (the Sargasso Sea and South Atlantic Gyre in the Atlantic and the North Pacific Subtropical and South Pacific Subtropical Gyres in the Pacific). In the far north, the Arctic Ocean ecosystem is a distinct ocean basin covered by ice, and the Southern Ocean around Antarctica is separated from the circulation of the Atlantic, Indian, and Pacific Oceans by the cyclonic circulation of the Antarctic Circumpolar Current.

As with terrestrial environments, marine ecosystems may be classified by their characteristic primary producers, i.e., single-celled phytoplankton that float in the surface layers of the ocean, marsh grasses, seagrasses, mangrove trees, seaweeds such as those forming kelp beds, the single-celled plants called zooxanthellae that live symbiotically with corals, and the chemosynthetic bacteria living in water, sediments, or symbiotically with other organisms at hydrothermal vents or other seep environments rich in chemically reduced compounds such as sulfides or methane.

Using combinations of coastline, coastal bathymetry, ocean current systems, surface winds, and biota, the near-surface pelagic layer of the ocean where primary productivity occurs has been classified into 51 provinces (Figure 1) by Longhurst (1998). Similar criteria have been used to classify coastal areas (Briggs, 1974). Marine sediments cover almost the entire surface of the ocean floor, yet a consistent global biogeographic classification of these benthic ecosystems has yet to be developed (Snelgrove *et al.*, 1997). In 2007, a classification of Marine Ecoregions of the World (MEOW) was proposed by major international conservation organizations (Spalding *et al.*, 2007). Twelve realms were divided into 62 provinces which were further divided into 232 ecoregions.

Comparison of Marine Environments with Land

The ocean occupies 71% of the surface area of the globe and the deep sea at depths below 200 m occupies 63.5% of the earth's surface. Seawater is 830 times more dense than air and supports most of the biomass in the ocean. The volume of seawater in the ocean provides 99.5% of the livable volume of the earth (Cohen, 1994).

Concentrations of near-surface chlorophyll in the ocean are measured according to wavelengths of light reflected from the surface of the ocean, which are sensed by earth-orbiting satellites. Extensive studies of the relationship between near-surface chlorophyll and primary production allow

satellite-derived information on chlorophyll to be converted to maps of primary productivity. Until very recently, overall primary production was thought to be approximately half that on land. Using distribution of chlorophyll in satellite photographs and models, primary productivity of the oceans has been shown to be about the same as that on land ($\sim 45\text{--}50 \text{ Pg C per annum}$ in the ocean and $\sim 55 \text{ Pg C per annum}$ on land; Falkowski *et al.*, 1998). For regions without ice cover, average net primary productivity (NPP) per area in the ocean is a third of that on land (ocean: $140 \text{ g C m}^{-2} \text{ yr}^{-1}$, and land: $426 \text{ g C m}^{-2} \text{ yr}^{-1}$). Only about 1.7% of the ocean surface area has NPP greater than $500 \text{ g C m}^{-2} \text{ yr}^{-1}$ compared to 25% for land. Most productivity in the marine environment is from phytoplankton. Attached, multicellular algae contribute only about 2%. The highest productivity occurs in estuaries and upwelling areas – these highly productive areas contribute approximately 18% to net ocean primary productivity. In the open ocean, the greatest primary productivity is near the equator and at mid-temperate latitudes in the Northern Hemisphere where there are regional maxima in terrestrial productivity. A smaller peak in productivity occurs in the Southern Subtropical Convergence where physical processes supply high concentrations of nutrients to surface waters (Falkowski *et al.*, 1998; Field *et al.*, 1998).

Marine primary producers are small and mobile whereas terrestrial primary producers are mostly large and rooted in the ground – trees account for approximately 80% of the primary production in terrestrial systems. By contrast, in central ocean gyres, photoautotrophic bacteria less than $2 \mu\text{m}$ in diameter and short generation times account for most of the primary production. Oceanic biomass is extremely dilute and filtering of organic particles is an important mode of feeding in marine environments.

Oceanic food webs have an average food chain length of nearly six trophic links as opposed to four trophic links in terrestrial systems (Cohen, 1994). The number of species of smallest marine organisms, such as the various groups of

Figure 1 Pelagic biomes. Reproduced from Longhurst A (1998) *Ecological Geography of the Sea*. San Diego, CA: with permission from Academic Press.

one-celled marine organisms, are extremely poorly known. The relationship between the spectrum of individual body size and the spectrum of rates of population growth differs in marine and terrestrial systems (Figure 2). In open ocean food webs, the hierarchy of size is not apparent at the lower trophic levels because of the broad overlap in size of consumers and primary producers (Figures 3 and 4, Karl, 1999).

The pattern of temporal variability of the physical environment differs between oceans and land. Marine ecosystems are characterized by about the same environmental variation over weeks and years as over days – variability is constant at frequencies ranging from days to decades. In terrestrial environments the variance of environmental parameters (e.g., temperature) increases steadily from frequencies of hours to millennia. Beyond 50 years the variance increases

with increasing frequency as it does over the entire time spectrum on land (Steele, 1985).

On land, individual organisms have a high probability of surviving the relatively predictable patterns of environmental variation that occur over time periods up to decades. For example, individual trees and many vertebrate animals resist adverse effects of variation at all frequencies up to several decades because of their large size and long generation time. In the open ocean, time series measurements at a single station and satellite measurements of ocean color from space show that net primary production varies significantly on periods from days to decades (Karl, 1999; Behrenfeld *et al.*, 2006). Both seasonal and daily differences in cloud cover may result in three-fold variation in light at the surface. Vertical displacements of phytoplankton by internal waves further increase the amount of light absorbed by seawater before it reaches the photosynthetic organisms, creating a further source of variability. Small bacterial and flagellate primary producers have reduced the adverse effect of this variation in light by supplementing their diet from the pool of dissolved organic matter excreted by other organisms.

Other distinctive features of marine populations are outlined by Cohen (1994) and in a US National Academy of Sciences book on marine biological diversity (National Academy of Sciences, 1995). Plant and animal populations in marine ecosystems generally spend part of their life cycle as floating or swimming stages in the plankton. Unlike most terrestrial systems, the connections between benthic and planktonic life-history stages assume great significance and there is an unusually broad range of dispersal abilities, reproductive rates, and generation times. Almost all species have the ability to disperse in the water column as larval stages produced by some form of sexual reproduction. As a consequence, marine ecosystems are largely open and distant marine habitats can be linked by dispersing larvae. Terrestrial systems are more localized functionally and localized extinction of species occurs more frequently. Invertebrate predators and grazers generally have very high reproductive output, which makes population fluctuations more likely. Fluctuations at the highest trophic levels affect interactions among species at successively lower trophic levels. This cascading effect often has unpredictable consequences, and even the lowest trophic level of primary producers may be controlled from the top down. Bottom-up control of food webs is exerted through the effects of nutrients and physical processes on primary productivity.

Biodiversity of Marine Ecosystems

Higher Taxa

The three main biological lineages are the Bacteria, Archaea, and Eukarya (includes plants, fungi, protists, and animals). Recent advances in molecular-biological techniques permit the first measurements of highly diverse oceanic assemblages of bacteria and archaea that cannot presently be cultured in the laboratory. Bacteria are more abundant in the photic zone and Archaea are more abundant in deeper water.

The Eukarya (all taxa except the Bacteria and Archaea) are divided into 71 well-defined monophyletic groups with no

Figure 3 Representative classification of planktonic organisms by size showing the diversity of various autotrophic and heterotrophic groups. Size, *per se*, cannot be used to separate autotrophs from heterotrophs in North Pacific Subtropical Gyre plankton assemblages. Courtesy of Albert Calbet in Karl DM (1999) A sea of change: Biogeochemical variability in the North Pacific Subtropical Gyre. *Ecosystems* 2: 181–214.

apparent taxonomic affinity with one another on the basis of cell organization (Patterson, 1999). Each of these groups includes taxa formerly assigned to the protists. By this classification animals and their relatives the choanoflagellates, and fungi and their relatives the chytrids, are defined as a single group. Plants are in another group altogether with 11 categories (~7000 species) of green algae.

Important groups of primary producers have affinities with several other monophyletic groups. The red algae are a distinct group with about 4000 known species; the ~1000 species of dinoflagellates are related to the ciliates. The ~10,000 species of diatoms are in a highly diverse lineage that includes kelps and other brown algae. The conspicuous red, green, and brown seaweeds of rocky shores are divided among three separate lineages. The two most important primary producers in the open ocean were formerly called blue-green algae. They are actually prokaryotic bacteria in two groups: the *Synechococcus* with three lineages, and the *Prochlorococcus* group with two lineages. These organisms account for most of the

phototrophic standing stock and primary production in the open ocean (Andersen *et al.*, 1996).

Among the many non-photosynthetic unicellular marine organisms, the ubiquitous Foraminifera are common both on the bottom at all depths and as pelagic organisms. Two abundant, poorly described benthic groups, the Komokiacea and the Xenophyophora (~40,000 known species), are big enough to be seen on the surface of deep-sea sediments. A leaflike form of Xenophyophora may be as large as 25 cm in diameter. These groups are separate lineages with no obvious relatives.

In the classification of marine, free-living, multicellular animals there are 31 phyla. Table 1 (modified from May and Godfrey, 1994) compares the described diversity and abundance among marine benthic, marine pelagic, freshwater, and terrestrial environments. Of the 31 known phyla, all are known to have lived in the ocean and 14, or about half, are known only from the ocean. Living representatives of the Phylum Onychophora are presently found only on land in

Figure 4 Schematic representation of the oceanic food web showing, on left, the classic pathway of carbon and energy flow through the photosynthetic eukarya to herbivores and on to higher trophic levels. Depicted on the right is the microbial food web, which uses energy stored in the nonliving, detrital carbon pool to produce microbial biomass that can re-enter the classic pathway of carbon and energy flow. Cell-associated ectoenzymes (ECTO) enable bacteria to use high molecular weight (HMW) dissolved organic carbon DOC in addition to the more traditional low molecular weight (LMW) and gaseous carbon substrates. Also shown in the microbial food web are viral particles and Archaea. At the present time, there is only rudimentary knowledge of the role of Archaea in the oceanic food web. Shown at the bottom of this diagram is the downward flux of particulate carbon (and energy), which is now thought to fuel most subeuphotic zone processes. The classic algae–herbivore grazer pathway is most important in this regard. Reproduced from Karl DM (1999) A sea of change: Biogeochemical variability in the North Pacific Subtropical Gyre. *Ecosystems* 2: 181–214, with permission from Springer.

the Southern Hemisphere, but are also known from fossil organisms that lived in the ocean more than 300 million years ago. Species diversity on land is dominated by insects and trees, groups that play a significant role only at the margins of the marine environment. Only about 15% of described species are found in the marine environment, but this may reflect the much greater cumulative effort devoted to species descriptions on land, rather than an actual difference in the number of species (May and Godfrey, 1994).

Species

Species are the units of evolution and both within-species and between-species genetic variation provided the bases for evolutionary change. For whole collections, species diversity is measured as the number of species and their relative abundances within and between habitats, regions, or other ecological or geographical units. Species richness is measured by collecting enough samples to represent very large numbers of individuals over very large areas. Ideally, communities should be sampled until the rate at which new species are found declines, and a plot of species versus area approaches a constant number of species. This level of sampling effort is achieved for groups with few rare species (e.g., larger animals including most vertebrates, planktonic organisms, and macrophytic plants). For species-rich taxa of bottom-dwelling invertebrates from coral reef or deep-sea habitats, this level of

sampling has not been attained. Where habitats are patchy and the vast majority of species are rare, it is seldom possible to collect and process enough samples to estimate species richness accurately.

For individual samples, indices based on the absolute number of species and the relative abundance of species are used to study species diversity. The most commonly used index is the Shannon–Wiener information function, H' , which equals the frequency of each species $p_i = s_i / \sum s_i$ multiplied by $\log_2 p_i$ summed over the number of species (n) collected (e.g., $\sum p_i \log_2 p_i$). Another measure, Hurlburt rarefaction, calculates a species versus individuals curve for each sample based on the expected number of species in successively smaller subsamples drawn from an actual sample. These species diversity curves are especially useful in comparing samples of unequal size.

There are approximately 200,000 described species of animals in the marine environment (Table 1). The most species-rich and least well known areas are coral reefs and the sediments of the deep-sea floor. There are no precise estimates for these environments but estimates for coral reefs alone exceed 600,000 species (Reaka-Kudla, 1997). Based on quantitative analysis of 233 box core samples from the Atlantic Ocean continental slope and rise off the east coast of North America, Grassle and Maciolek (1992) estimated 1 to 10 million macrofaunal species in the deep sea (Gage and Tyler, 1991). May and Godfrey (1994) estimated 0.5 million based on the portion of species previously undescribed in the Grassle and Maciolek study. Poore and Wilson (1993)

analyzed samples from the Southern Pacific Ocean off Australia and, on the same basis, estimated that there are 5 million species in deep-sea sediments. Multicellular animals small enough to pass through a 1-mm sieve (meiofauna), such as nematode worms, are even less well known and Lamshead has argued that there may be 100 million species if nematodes are included (Lamshead *et al.*, 1994). Reasons for high diversity of species in the oceans include their long evolutionary history, the vast area of deep-sea floor ($3 \times 10^8 \text{ km}^2$) with relatively few barriers to dispersal, and the episodic nature of patch formation within and between habitats on a variety of spatial and temporal scales.

Genes

Genetic diversity is the heritable variation among individuals measured as allelic diversity at a broad sampling of genetic loci or as genetic sequence information at the molecular level

within populations. Genetic variation occurs among subpopulations as well as within populations. Differentiation among subpopulations results from natural selection for genetic variants adapted to local patterns of environmental variation or random loss of genetic variants in small isolated subpopulations. Species with relatively high rates of dispersal are less likely to form subpopulations and species with very poor dispersal ability are more likely to diverge from parent populations as a result of random processes. In coastal areas, genetic divergence is related to the length of life of dispersal stages and barriers to current flow from one place to another along a coastline. For some shallow-water species, genetic isolation of island populations is related to distances among islands. The archipelagos in the central Indopacific in the vicinity of Indonesia and Papua New Guinea have a high richness of species, which then declines eastward to relatively isolated peripheral island archipelagos (Stehli, 1965). In the same region, in a study of population differentiation in four species of sea urchins, Palumbi (1997) found high genetic diversity (mitochondrial DNA sequence diversity) in the central area (1.6% variation among individuals) and much lower genetic diversity (0.5% variation among individuals) in peripheral island localities to the east. For these species, genetic diversity and species diversity co-vary across gradients suggesting a similarity in the processes maintaining gradients in diversity despite different mechanisms for the origin of the variation. Fluctuations in population size in relatively isolated populations could result in both loss of genetic variants and reductions in number of species (Palumbi, 1997).

In the deep ocean, hydrothermal vents are analogous to islands in the sense that the fluid flows support widely separated biological communities, linearly aligned along the Mid-Ocean Ridge. The patterns of deep-sea ocean currents that transport dispersal stages of species restricted to hydrothermal vents are poorly understood, but it is possible to make estimates of gene flow from the extent of genetic differentiation among populations of individual species. The flow of hydrothermal fluids, containing energy-rich reduced compounds such as hydrogen sulfide, supports chemosynthetic primary productivity. At East Pacific Rise vents, the flow of hydrothermal fluid may last only a decade or two at any one site and all populations are maintained by dispersal over considerable distances. Species can be divided into three categories: those that show no geographic pattern of genetic differentiation, those that are isolated by distance, and species without a free-living larval dispersal stage, which apparently have good dispersal to sites along a single ridge segment but poor dispersal between separated ridge segments (Vrijenhoek, 1997). The latest methods for measuring genetic diversity are being applied to increase numbers of marine species and rapid advances can be expected (DeSalle *et al.*, 2005).

Ecosystem Function

It is useful to classify members of species assemblages according to their feeding relationships with other species in the ecosystem. A trophic unit includes all species that eat the same kinds of foods or are consumed by the same kinds of consumers. Within a food chain, there is a hierarchy of consumers

from primary producers to primary consumers followed by a further sequence of consumers. Each step in a food chain results in a reduction in biomass, and simple food chains are often described as a pyramid with plants at the base and apex predators at the top. In the water column, unicellular phytoplankton form the first trophic level of marine food chains. The second level is formed by herbivores and detritivores and subsequent levels are formed by successive levels of predators. Species at the highest trophic levels can affect the food web relationships among species at lower levels. For example, removal of a top predator can have cascading effects on herbivores and ultimately on primary producers.

Because of the dilute seawater medium, a great many marine species have developed both active and passive means for filtering or trapping food particles from the water. Copepods, the most common animals in the water column, have filtering appendages and gelatinous zooplankton cast mucous nets to feed on phytoplankton. Baleen whales filter zooplankton (krill) from the water column. On the sea bottom, clams and sea cucumbers pump water past internal filters and many animals in sediments pump water through their burrows in order to feed. Other bottom animals have appendages protruding above the sediments that trap or filter food particles. In many marine organisms, the distinction between producers and consumers is blurred. Reef-building corals use their tentacles to trap zooplankton yet may take most of their sustenance from photosynthetic dinoflagellates living symbiotically in their tissues. Other animal-plant relationships of this sort are found in tropical clams and one-celled radiolarians and foraminifera.

Some marine species play another important functional role by providing habitat for other species, either on a large spatial scale – as with coral or coralline algae reefs, polychaete worm reefs, oyster reefs, seagrasses, kelps, marsh grasses, and mangrove trees. On a smaller scale, biogenic sediment structures (tubes, burrows, mounds, fecal aggregations) and more persistent structures made by tube builders, sponges, or shell-bearing animals may serve as habitat for other species.

Some species significantly affect the ecosystem by regenerating nutrients that limit primary production. Burrowing animals release nutrients into the water column which stimulate phytoplankton growth. In chemically reduced sediments, animals pump water into sediments for respiration or feeding and supply oxygen to chemosynthetic primary producers living in the burrow. The role of single species is often not obvious, and several different criteria may be used to assign species to functional groups within an ecosystem (Braeckman *et al.*, 2010). In general, redundancy of ecosystem function within a functional group has the potential to stabilize ecosystem processes despite fluctuations in the environment. Loss of functional groups implies drastic changes in ecosystem function.

Ecosystem Diversity

Edge of the Ocean

Intertidal Beaches

Beaches can be classified according to topography, organic content of sediments, and wave action. Reflective beaches are

dominated by low wave energy, low organic content, and coarse sand. Reflective beaches have waves 1 m high or less and are generally found on open coasts with deep embayments, on tropical coasts, and on the coasts of polar seas. Surging wave action filters and drains large volumes of water through the interstices of the sediments, resulting in well-flushed and highly oxygenated coarse sand deposits (Alongi, 1998). Dissipative beaches, at the other extreme of a continuum, are produced by a combination of high waves (>2.5 m) and fine sand deposits with higher amounts of organic matter. These are common on the west coasts of Australia and Southern Africa and seasonally on the west coast of North America where high wave swells and fine sands are abundant. Extensive intertidal sand and mudflats are common on dissipative beaches.

Many beaches have adjacent seagrass beds, kelp beds, or other sources of macro-detritus, which are deposited as thick layers of wrack on the beach. These accumulations support communities that include both marine and terrestrial invertebrates (e.g., beach hoppers, beetles, and kelp-fly larvae). Other beaches are characterized by growth of diatoms in the sediments and inputs of small, filterable organic particles. Many animals live in the sediments, and in some high energy situations animals such as mole crabs and small bivalves move up and down the beach with the tides filtering particles from the waves. Large sand flats, such as in the Wadden Sea in the Netherlands, may be especially productive and support high standing stocks of grazing invertebrates.

Kelp Beds

Kelps attach to the bottom and form a surface canopy at depths up to ~20 m. Under the most favorable conditions these large marine plants form subtidal forests and attain rates of primary production in excess of $1000 \text{ g C m}^{-2} \text{ d}^{-1}$. These forests provide protection and food for a rich community of fish and invertebrates. The biomass and abundance of kelps may be regulated by sea urchin consumers. Sea otters play an important role in maintaining kelp forests by controlling the abundance of sea urchins. In the absence of sea otters, kelp forests are reduced by urchins to a pavement of encrusting algae and sea urchins. Kelp forests are important nursery areas for many species of fish and their detrital production enhances the abundance of benthic populations (United Nations Environmental Programme, 1995). Kelp populations are influenced over large scales by oceanographic climate. Nutrient-rich conditions during La Niña years result in increased growth and reproduction of the competitively dominant, canopy kelp species, *Macrocystis pyrifera*. Inter-decadal-scale shifts in community composition result from fluctuations in kelp density (Dayton *et al.*, 1999).

Rocky Shores

Rocky coasts exposed to the open ocean are characterized by wave action resulting in communities of attached seaweeds and filter-feeding invertebrates such as bivalve mollusks (e.g., mussels), barnacles, and tunicates that provide physical structure for other species. Wave energy enhances the productivity of these ecosystems by continually renewing nutrients and food. The shore face and the organisms that reside on the shore can be divided into zones according to tidal height and

length of exposure to air and the interactions of the dominant species with herbivores such as snails (gastropod mollusks) and predators (particularly snails, starfish, and birds). The large-scale pattern of rocky-shore communities depends on the distribution of rocky outcrops and sporadic changes in climate resulting in unusually heavy waves, ice cover, or sedimentation from rivers. The interaction of physical change and biological relationships among species at a variety of spatial scales (from local to regional) and temporal scales (from annual storm events to inter-decadal climatic change) are most thoroughly understood for rocky intertidal ecosystems.

Coral Reefs

Coral reef ecosystems occur where conditions are favorable for growth of reef-forming corals with dinoflagellate primary producers living symbiotically in their tissues. Growth of corals over many generations in geologic time results in major limestone structures such as coral atolls or the Great Barrier Reef off Australia. Dense growths of coral can sometimes occur in the deep sea, but these species lack photosynthetic symbionts, grow relatively slowly, and do not form major reef structures.

Reefs grow in strong light and clear water at temperatures from 18 to 30 °C at latitudes between 30° N and 30° S. Coral reefs are adversely affected by high nutrient concentrations, runoff of sediments from land, direct removal, and overfishing. The average primary production of corals in combination with their symbiotic dinoflagellates is about 25 g C m⁻² d⁻¹ and varies greatly from species to species. Over large areas, net primary productivity of the most actively growing reef crests and slopes ranges from 1 to 5 g C m⁻² d⁻¹.

Reefs support an enormous species richness and complexity of interactions among species. Conspicuous large animals include enormous coral heads and large fish such as groupers, stingrays, and manta rays. Many of the colorful reef fish do not move far and develop complex behavioral relationships both within and between species. Some live symbiotically with other species, for example, individual anemone fish live in close association with patches of anemones. Cleaner fish set up cleaning stations where they feed on the ectoparasites attached to the gills of other fish. Some species mimic the cleaner fish and take bites out of the fish expecting to be cleaned of parasites.

Continental Shelves

Continental shelf coastal areas, on the order of 10,000 km² or more, have been called "Large Marine Ecosystems" (Sherman, 1993). These are separated from other areas of the ocean by continental shelf depth and ocean currents, and the shapes of coastlines form major seas, bays, or gulfs. Examples include the Baltic, North, Mediterranean, Black, Caspian, Red, Arabian, Barents, Bering, Okhotsk, Japan, Yellow, East China, Sulu, Celebes, and Caribbean Seas; the Bay of Bengal and Walvis Bay; and the Gulfs of Alaska, California, and Mexico. Primary productivity in these systems ranges from less than 35 g C m⁻² yr⁻¹ in the low latitude, warm waters of the Red Sea and high latitude, cold waters of

the Beaufort Sea (10–20 g C m⁻² yr⁻¹) to the very high primary productivity of Eastern Boundary Current upwelling areas in the Southern Hemisphere (1000–2000 g C m⁻² yr⁻¹) in the Peru Current and Walvis Bay (Walsh, 1988). Most of the world's major fisheries are on continental shelves in mid-latitudes.

The Open Ocean and Deep Sea

Pelagic

The largest ecosystems in the ocean are the central gyres of the Atlantic, Pacific, and Indian Oceans. Ecosystem processes in the North Pacific Subtropical Gyre (NPSG) have been summarized by Karl (1999). This ecosystem is the largest circulation feature on the planet (2×10^7 km²) and one of the most persistent, its boundaries having remained approximately the same for the past 10⁷ years. The NPSG has a clockwise circulation of less than 4 cm s⁻¹ and forms a circumscribed, stable, and relatively homogenous habitat. The surface mixed layer varies from 40 to 100 m depth and is characterized by surface temperatures of 24 °C or higher, low nitrate concentrations but relatively high dissolved organic nitrogen, and low standing stocks of organisms. The zone of primary productivity can be divided into two layers: an upper layer where chlorophyll increases in the winter and decreases in the summer, and lower layer (100–175 m), where chlorophyll increases in the spring and declines in the fall. Recharge of nutrients is from deeper water as a result of vertical eddy diffusion and episodic mixing events. This leads to considerable spatial variability in mixing processes and nutrient concentrations that vary by as much as three orders of magnitude. Phytoplankton primary production was once thought to be mostly by eukaryotes (diatoms and flagellates), but is now known to be more than 90% from the small bacterial taxa *Synechococcus* and *Prochlorococcus*. The standing stocks of these autotrophic bacterial groups comprise 80% of chlorophyll *a* and feed a microbial loop that internally regenerates nutrients and maintains a pool of dissolved organic matter, which supports them (Figure 4). The abundance of these autoheterotrophs is controlled by light, nutrients, and predation by bacteria and a mixed assemblage of protists. Viral infection may also be an important source of mortality for these organisms. Archaea are abundant but it is not clear whether they are significant chemosynthetic primary producers because little is presently known about these organisms.

Very little organic matter escapes remineralization and the microbial loop provides negligible subsidy to the rest of the food web. The classic food chain pathway of eucaryote phytoplankton to copepod herbivores and on to higher trophic-level fish is ephemeral and occurs more frequently in surface waters during the summer. Organic matter produced by the eucaryotic phytoplankton food chain constitutes most of the exportable carbon during aperiodic, pulsed events.

Falkowski *et al.* (1998) have summarized the biogeochemical processes controlling primary production in the open ocean. The central ocean gyres in the Atlantic, Pacific, and Indian Oceans have been considered analogous to deserts on land with low primary productivity and contain only ~0.2 mg m⁻³ of chlorophyll. Coastal upwelling regions,

seasonally mixed regions of temperate and boreal seas, divergent subpolar gyres, and meso-scale features with eddy-induced pumping have sufficient vertical flux of nutrients to support 5 mg m^{-3} of chlorophyll. Throughout most of the coastal and open ocean, primary production is limited by the availability of inorganic fixed nitrogen. In some instances, the cyanobacteria that fix nitrogen in the open ocean are limited by iron and an important source of iron to the ocean is dust carried from land by winds. Limitation of primary production by lack of iron is especially notable in the South Pacific (Falkowski *et al.*, 1998). There has been a lively debate about using iron fertilization on a large scale as a geo-engineering solution to increasing levels of atmospheric CO_2 . A series of short-term, small-scale open ocean iron fertilization experiments have provided useful information on open ocean ecosystems but have not supported this as a CO_2 -mitigation strategy (Strong *et al.*, 2009)

Benthic

The deep-sea floor is divided into major ocean basins by continents and the Mid-Ocean Ridge. Communities within ocean basins may be further divided according to depth, sediment type, and level of energy of deep-sea currents. The deep ocean floor is the least-known part of the planet but, through use of manned and unmanned submersibles, distinct ecosystem processes at hydrothermal vents, continental margin seeps, sea-mounts, ocean trenches, and areas of strong bottom currents are being explored and described.

The largest ocean basins and deep ocean trenches each have some species that live only in that basin and nowhere else. Hydrothermal processes along the Mid-Ocean Ridge mix seawater through porous rock at high temperatures yielding an energy-rich fluid containing reduced compounds. These compounds support chemosynthetic microorganisms that provide primary production for a discrete ecosystem clustered around each hydrothermal vent. Flows of subsurface fluid seep out of sediments deposited along some ocean margins providing similar energy-rich fluid to chemosynthetic organisms.

The food supply for most of the deep sea comes from the productivity of surface waters. When diatoms bloom, or gelatinous animals such as salps multiply rapidly, they die and sink, so that organic material accumulates in low areas of the uneven surface of the sea floor and in burrows and depressions left by the larger inhabitants. Even in the central ocean gyres where export production is low, the dead remains of fish, marine mammals, or terrestrial plant material carried seaward sink and form widely separated organic patches on the sea floor. Species respond to these patches at different rates and the probability that two species reach the same patch at the same time is low. This reduces the likelihood of species competing and of one species eliminating another. Most deep-sea species are small and many, including most fish species, are relatively slow growing, long lived, and late in maturation. Attempts to sustain deep-water fisheries have proven unsuccessful because low rates of population growth cannot keep up with rates of removal.

Species that grow relatively fast characteristically respond to patchy but concentrated sources of food from the ocean surface, such as wood from rivers, or the bodies of pelagic animals that settle to the bottom (Baco and Smith, 2003). For

example, wood-boring bivalves rapidly colonize pieces of wood, grow to maturity in a few months feeding on their wood habitat, and produce thousands of eggs and larvae to colonize the next piece of wood that settles to the sea floor (Turner, 1973). Other species of bivalves grow very slowly in relatively homogeneous sediments, take several decades to reach maturity, and may produce only one egg at a time (Turekian *et al.*, 1975) in contrast to the rapid maturation and production of millions of eggs by most shallow-water bivalves.

Submarine canyons form conduits for sediment from continental shelves into the deep ocean. Unpredictable events of sediment erosion or scouring by intense currents result in relatively few species in the soft sediments at the bottom and sides of canyons. Seamounts are under sea mountains formed by the same processes at the hot spots on the ocean floor that form volcanic islands. Seamounts often support large populations of fish, and more than 70 species of commercially important fish have been reported. Interactions of currents with the steep topography of seamounts result in areas of enhanced primary productivity and high abundances of zooplankton that provide food for fish and dense concentrations of suspension-feeding benthic invertebrates (Rogers, 1994).

Mid-Ocean Ridges and Hydrothermal Vents

The 40,000 nautical mile Mid-Ocean Ridge system is the largest feature on the deep-sea floor. In 1977 a unique ecosystem was discovered at sites where a plume of high-temperature fluid rich in reduced compounds pours out into the water column. It is now known that sulfur oxidizers are among the most numerous bacteria and form a major base of the food chain. Other energy sources include hydrogen sulfide, methane, and reduced metals such as iron and manganese. In the Pacific, large, red-plumed worms up to 2 m long and large clams and mussels dominate the vents. These animals feed on organic compounds produced by symbiotic sulfur bacteria living in their tissues. Vents in the Atlantic have some of the same kinds of animals, but the most conspicuous are shrimp, which swarm over the surface of vent chimneys. Vents usually have a restricted distribution on any given ridge segment and persist for about 10–20 years, until there is local extinction of the vent community. Animals colonize new vents rapidly, grow fast, and produce enough offspring to colonize the next vent. In comparison with the rest of the deep sea, few species have adapted to the extreme thermal (4°C up to temperatures in excess of 150°C), chemical (high concentrations of cadmium, lead, cobalt, and arsenic) conditions at hydrothermal vents (Grassle, 1986). Most species found at hydrothermal vents live exclusively in this environment. Of the 443 species found at hydrothermal vents, 15 have been found in other sulfide-rich environments and only 30 species are known from elsewhere in the deep sea (Tunnicliffe *et al.*, 1998).

Potential Consequences of Anthropogenic Change

Eutrophication

Eutrophication is the increase in the rate of supply of organic matter to an ecosystem. Increases in global inputs of

nitrogenous fertilizers and the mining of phosphate rock have generated increased concern about the effects of eutrophication on enclosed marine ecosystems (Nixon, 1995). Eutrophic ecosystems have algal production in excess of $300 \text{ g C m}^{-2} \text{ yr}^{-1}$, which results in areas of anoxia and loss of habitat for fish and other organisms. Relatively high rates of denitrification on continental shelves remove excess nitrogen originating from land sources and, in concert with dilution, help prevent adverse eutrophication effects in open coastal areas (Soetaert and Middelburg, 2009).

Overfishing

Globally, about 30% of commercial fish stocks are over-fished and another 44% are being fished at or near the maximum potential long-term catch rate. Atlantic halibut, cod, orange roughy, and many species of salmon are now severely depleted. Significant changes in community structure as a result of overfishing have occurred in ecosystem structure in the Bering, Barents, and Baltic Seas (National Academy of Sciences, Committee on Ecosystem Management for Sustainable Marine Fisheries, 1999). Bottom-fishing has been shown to result in physical destruction of some bottom habitats. Efforts to reverse the effects of over-fishing and habitat destruction may be having some positive effects in certain ecosystems (Worm *et al.*, 2009).

Overfishing has resulted in major changes in coral reef ecosystems. Normally, herbivorous fish heavily graze the attached algae, ensuring enough open reef surface for corals to settle and grow. This is especially true following major storms when wave action reduces coral coverage and circumstances are favorable for rapid algal growth. In the Caribbean, under normal circumstances, sea urchin grazing may compensate for reductions in fish grazing. A combination of overfishing and the decimation of sea urchin grazers by disease favored algal growth following a hurricane, which resulted in reefs dominated by algae (National Academy of Sciences, 1995). Recent research on coral-algal competition, in combination with the effects of no-take marine protected areas, have provided many insights into the positive and negative interactions among members of coral reef food webs (Hughes *et al.*, 2007; McCook *et al.*, 2010).

Invasive Species

Unwanted, non-indigenous species are often introduced to new geographic regions, both deliberately to start new fisheries and accidentally through release from aquaria or ballast water carried by ships, sometimes with disastrous consequences. The Asian clam became established in the San Francisco Bay in 1986 and quickly displaced other species from large areas of the seabed and altered the water chemistry of the bay (National Academy of Sciences, 1995). The introduction of predatory green crabs to coastal environments on the east coast resulted in major reductions in shellfish beds and the green crab has become invasive in many other areas. In short, invasive species have become a significant problem in many marine coastal environments and considerable effort is needed to curb this severe problem (Ruiz *et al.*, 2000).

In summary, the oceans encompass a broad array of habitats that differ in their diversity, function, and

vulnerability. Much of the vast area of the oceans is poorly described, but we have some understanding of a variety of globally essential ecosystem processes and predictors of biodiversity (Tittensor *et al.*, 2010). Species loss may threaten not only the organisms themselves but also the many ecological processes that serve the rest of the planet and its human populations.

Glossary

Alien: introduced, exotic, nonindigenous, nonnative, invasive species A species that has been transported by human activity (i.e., mariculture), intentionally or accidentally, to a site at which it does not naturally occur.

Ballast Water Water carried by a vessel to improve stability.

Benthic Organism An organism pertaining to the seabed; bottom-dwelling.

Biodiversity The variability among living organisms from all sources and the ecological systems of which they are a part.

Disturbance Any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment.

Ecosystem A complex nonlinear community of organisms in their physical environment.

Ecosystem Engineer Species Species that directly or indirectly modulate the availability of resources (other than themselves to other species) by causing physical state changes in biotic or abiotic material and in so doing modify, maintain, and/or create habitats.

Eutrophication Enrichment of a body of water with nutrients causing excessive growth of phytoplankton,

seaweed, or vascular plants and often accompanied by a depletion of oxygen.

Food web, Trophic web A network of interconnected trophic chains in a community. A network of consumer–resource interactions among a group of organisms, populations, or aggregate trophic units.

Guild A group of species having similar functional roles in the community (e.g. herbivores).

Keystone species A group of species whose effects on the structure, dynamics, and functioning of the community is disproportionately large relative to its abundance.

Pelagic organism A free-swimming (nekton) or floating (plankton) organism that lives exclusively in the water column.

Resilience The resistance to a disturbance of a system and the speed of return to an equilibrium point, or the disturbance that can be absorbed before the system changes in structure by the change of variables and processes that control system behavior.

Species diversity The number of species in a given community (= species richness) and the way the species' abundances (i.e., number, biomass, and cover) are distributed among species (= species evenness).

Trophic level Feeding level in a food chain or pyramid (e.g., carnivores).

Introduction

The main threats to marine ecosystems are the human alteration of habitats, the excessive extraction of resources, pollution (Castilla, 1996), invasive species (i.e., introduction through mariculture and ballast water; Cohen and Carlton, 1998), eutrophication, and nonanthropogenic environmental changes (National Research Council (NRC), 1999; Castilla and Camus, 1992). Furthermore, multiple and compounded perturbations related to physically and biological based disturbances are resulting in communities entering new domains or “ecological surprises” (Paine *et al.*, 1998), with important modifications in their structure (i.e., species composition) and dynamics (i.e., alternative states).

Single, multiple, or compounded impacts on ecosystems may directly or indirectly affect their structure, including species diversity and functioning. Ecosystems are complexly linked nonlinear systems and their dynamics may be sensitive to past conditions and subjected to shifts when exposed to anthropogenic and nonanthropogenic environmental stress (NRC, 1999).

The concept of biological diversity (biodiversity; Heywood, 1995) is defined as: the variability among living organisms from all sources and the ecological system to which they are

part. The analysis of biodiversity considers four levels: genetic, species, community, and ecosystems. This article focuses on the species diversity (richness, the number of species in a given community; evenness, species abundance), community resilience, and ecosystem functioning. One of the best avenues to integrate species diversity functioning and community resilience (Holling, 1973) is to study their dynamics through long-term manipulations. The article reviews long-term experiments and impacts on marine communities and ecosystems in which humans are one of the key ecological factors (Castilla, 1999).

Human Impacts on Marine Communities and the Effects on Species Diversity and Functioning

Rocky Intertidal Communities

Castilla (1999), based on a 16-year intertidal human exclusion experiment in central Chile (Las Cruces fenced Marine Coastal Preserve; ECIM), summarized the ecological roles played by humans as top predators on rocky mid-intertidal marine communities. The functional intertidal food web, without

humans (inside the ECIM preserve) and with humans (outside ECIM), differed substantially. On these rocky shores the impact of intertidal food gatherers is significant (Durán *et al.*, 1986). The collectors target mainly the keystone muricid snail *Concholepas concholepas*, locally known as “loco” (Castilla *et al.*, 1998). The high density of locos inside ECIM, following its closure to collectors in 1982, resulted in strong loco predation on the competitive dominant mussel *Perumytilus purpuratus*, which cannot “escape in size” from its predator. Therefore, a few years after the fencing of ECIM, the original dense mid-intertidal mussel beds inside ECIM were almost completely eliminated by the locos (Castilla, 1999). The primary space, so liberated, was readily invaded by two species of barnacles, *Jehlius cirratus* and *Notochthamalus scabrosus*, and several species of algae. Despite the fact that the loco also consumes barnacles, they have persisted for several years since they have a “weed recruitment strategy” (Castilla, 1988): After removal they keep reinvading the shore. This is not the case for *P. purpuratus*, which requires special substratum conditions to reinvade the shore (Navarrete and Castilla, 1990). Following the closure of the rocky shore at ECIM, species richness and evenness of sessile organisms using primary substrata increased inside ECIM. Outside ECIM (control), under reduced loco density due to food gathering, primary space is still dominated almost exclusively by the competitive dominant mussel *P. purpuratus*, and the biological diversity of the sessile primary substrata users is reduced since the mussels are long-term winners and appropriate the rock resource (Figure 1). Castilla (1999) provided a detailed account of direct and indirect human impacts on these communities and discussed differences in their functioning. For instance, it was noted that the settlement of keyhole limpets, *Fissurella* spp., was indirectly negatively impacted inside ECIM since their recruitment substratum, the beds of the mussels *P. purpuratus*, were absent due to loco’s direct predatory impacts (Figure 1).

Nevertheless, in the papers previously noted, no mention was made that rocky intertidal species diversity should be viewed in a more comprehensive way so as to include the secondary substrata generated by *P. purpuratus*, an ecosystem engineer species (Jones *et al.*, 1994). Mussel matrices allow for the establishment of a rich macroinvertebrate and algal community composed of dozens of species (Paredes and Tarazona, 1980; Lohse, 1993) which live inside the matrices and on mussel shells. Although in central Chile this effect has not been evaluated, the *P. purpuratus* matrices enhance species richness (for southern Chile, see López and Osorio, 1977) in sites impacted by humans (outside ECIM) compared to those not impacted (inside ECIM, J. Castilla, unpublished results).

Similar ecological direct and indirect human impacts and drastic modification in rocky intertidal species evenness and intertidal community functioning (Figure 2) have been reported at Mehuín’s southern Chile coastal preserve (Moreno *et al.*, 1984). Lindberg *et al.* (1998), through manipulative and “natural” experiments, described a three-trophic-level interaction among the American black oystercatcher (*Haematopus bachmani*), limpets (*Lottia* spp.), and erect fleshy algae in rocky intertidal bench communities of central and southern California. Human disturbances, such as the selective collection of large-size limpets and the reduction of shorebirds (in shores frequented by humans), drive the communities to a state

dominated by small limpets and high cover of fleshy algae. Intertidal benches in relatively isolated islands (e.g., San Nicolas in central California) with large densities of oystercatchers and an absence of limpet human collection present communities in a different alternative state, which is characterized by large-size limpet populations and comparatively reduced fleshy algal cover.

Rocky Subtidal Communities

The Cape rock lobster *Jasus lalandii*, commercially the most important lobster species in South Africa, causes profound direct and indirect effects on subtidal competitive dominant mussel species, such as *Choromytilus meridionalis* and *Aulacomya ater* (Griffiths and Seiderer, 1980), severely modifying species diversity and community functioning. Barkai and Branch (1988a, b) compared the nearshore benthic communities of two adjacent islands on the west coast of South Africa: Malgas and Marcus Islands (33° S, 18° E), which are approximately 4 km apart. The biotas of both islands have been protected from human exploitation since 1929. In the 1960s both islands supported populations of rock lobsters, but later, due to overfishing, a management plan was established which included a catch quota. Currently, Malgas still supports an unusually dense population of *J. lalandii* (probably partly due to the management plan) with densities of up to 10 individuals per square meter, whereas Marcus has a very reduced adult population of lobster. The benthic communities of both islands have only 34% of species in common. The biota of Malgas is dominated by numerous species of algae, whereas that of Marcus consists of thick beds of the black mussel *C. meridionalis*, an autogenic ecosystem engineer species that has a rich and diverse associated fauna (Barkai and Branch, 1988a). At Malgas, the predatory lobsters have eliminated a large proportion of spatial competitors, including mussels and barnacles, and sea urchins are absent. As a consequence, macroalgae proliferated. At Marcus, due to the absence of lobsters, the competitive dominant *C. meridionalis* formed dense beds, outcompeting other species of mussels, such as *A. ater* and algae; sea urchins are common (Castilla *et al.*, 1994). Barkai and Branch (1988a, b) discussed this ecological situation and argued for the existence of alternative stable states on the contrasting islands. Figure 3 provides a summary of the main species involved, relative biomass, and direct, indirect, positive, and negative interactions between organisms on both islands.

The ecological impact of the Cape rock lobster at Malgas was experimentally demonstrated by Barkai and McQuaid (1988). The experiments showed that the drastic community differences between the islands were due to the dense population of lobster at Malgas and its absence at Marcus. In fact, the introduction of 1000 lobsters at Marcus ended amazingly: The lobsters were attacked by thousand of snails, *Burnupena* sp., which exist at Marcus in densities of up to 250 per square meter, and the lobsters perished within 30 min. This may explain their absence at Marcus, supporting the existence of an alternative ecological state.

In South African waters, it is unknown to what extent the commercial exploitation of rock lobsters or conservation

Figure 1 Diagrammatic representation of rocky intertidal food webs and human impacts outside (A) and inside (B) the Las Cruces (ECIM) Marine Preserve, central Chile. The size of the circles represents the approximate density of populations. An arrow with a single asterisk indicates predation. The point of the arrow shows the flow of energy and the width indicates strong (wide) or weak (narrow) interactions. A double-asterisk arrow represents interspecific competition and the point width indicates the long-term competitive dominant (wider) or subordinate (narrower) species (intraspecific interactions are not considered). Settlement is shown by dashed lines and the arrows on these lines show the settler facilitator. One asterisk indicates that barnacles and macroalgae, apart from their ability to settle directly on rock, settle on top of mussel shells. A double asterisk indicates keyhole limpet browsing on young barnacles. *Concholepas concholepas* is a carnivore muricid. *Fissurella* spp. are herbivore gastropods (reprinted from Castilla, Rocky intertidal food webs and human impacts © 1999, p. 281), with permission from Elsevier.

measures (i.e., coastal closures) have impacted the nearshore rocky subtidal communities or in how many cases (other than Marcus and Malgas Islands) alternative stable states have been reached. This is a classical example in which both extreme attitudes—overexploitation and total conservation (no-take areas)—can result in drastically different species diversity and community functioning, mediated by the role of a high-trophic-level predator.

Humans and Linkages between Coastal and Oceanic Waters

Enhydra lutris, the northern sea otter, is found in near-shore environments ranging across the Pacific rim from Hokkaido (Japan) to Baja California (Mexico). The exploitation of their pelts led to the near extinction of otter populations in approximately 1911, when unregulated hunting was ended. Since then, the recovery of otter populations has occurred, particularly in the Aleutian Island chain, where by the 1970s the populations reached near maximum densities in some areas, were growing rapidly in others, and remained absent from others. Otters as keystone species (Power *et al.*, 1996) control

the local biomass and the abundance of sea urchins, which regulate benthic algae biomass and productivity. Aleutian interisland comparisons (Estes *et al.*, 1998) have shown that kelp deforestation occurred in islands with low sea otter densities due to the increased density of sea urchins, whereas islands with high sea otter densities showed high kelp biomass. Estes *et al.* reported the complete transformation of a subtidal kelp forest in islands of the Aleutian Archipelago from three to four trophic-level systems and the release of sea urchin populations from the limiting influence of their predator, *E. lutris*. In the original circumstances, in the absence of sea otters, sea urchin populations increased rapidly and overgrazed the kelp forest, setting in motion a suite of different ecological impacts which drastically transformed the coastal ecosystems. These transformations had implications on the functioning of the communities and affected species diversity. Humans are highly involved in Estes *et al.*'s findings. In recent years in western Alaska, declines of *E. lutris* populations have been observed. The authors have argued that this is probably due to the recent increased predation on sea otters by killer whales, *Orcinus orca*. *Orcinus* may have initiated

Figure 2 Diagrammatic representation of rocky intertidal food webs and human impacts outside (A) and inside (B) the Mehuín's Marine Preserve, southern Chile. Symbols are as described in the legend to **Figure 1** (reproduced from Moreno CA (1986) Un resumen de las consecuencias ecológicas de la exclusión del hombre en la zona intermareal de Mehuín-Chile. *Estud. Oceanol.* 5: 59–66), with permission from universidad de Antofagasta.

predatory influences that cascaded down successively lower trophic levels, first through the reduction of densities of sea otters, which triggered the increase of sea urchin populations, and ultimately the depletion of kelp biomass due to overgrazing. Estes *et al.*'s paper includes documented information on declines of sea otter populations and increases in the density and intensity of grazing of sea urchins on the kelp beds. Sea otters and killer whales have cohabited the Aleutian Archipelago for millennia and Estes *et al.* attributed the sudden change of behavior of killer whales to a shift in their prey resource base. This has probably resulted from the collapse of pinniped populations, such as the Stellar sea lion and harbor seals, which were among the killer whale's main prey items. It has been suggested that the pinniped populations may have collapsed due to the Northwest Pacific midwater-trawl overfishing of walleye pollock (*Theragra chalcogramma*) (Alverson *et al.*, 1994) and/or increases in the ocean temperature. The authors recognized that some of their arguments contained speculations and that the critical one refers to the direct/indirect impacts of humans on marine ecosystems. In fact, sea otters, pinnipeds, and whales are under national and international protection in the Aleutians through different

treaties and agreements signed dozens of years ago, but it also has to be recognized that their food resources have been depleted independently through overfishing. For instance, there is evidence that in the case of the pinnipeds a reduction (population collapses in some cases) has occurred mostly due to overfishing of pinnipeds, or of their fish resources, and also to climate changes. Overfishing is directly linked to human activities, and in Estes *et al.*'s scenario, humans and not killer whales may be considered as the apex predator. Humans have redirected the functioning of oceanic and coastal marine ecosystems in these localities and modified trophic linkages.

These examples indicate that there are at least two aspects of human ecological influences on marine communities that are difficult to evaluate and hence demonstrate an indisputable cause-effect situation. First, in many cases, the functioning of the marine communities is affected indirectly by anthropogenic activities—for example, human overfishing of pinniped's fish resources, collapse of pinniped populations, a shift in the prey item of killer whales, predation on the sea otter, population explosion of sea urchins, and overgrazing of kelp beds. The cascading down to successively lower trophic levels is complex and requires long-term observation and experiments

Figure 3 Rock lobster direct (+) and indirect (-) effects on mussel, welk, and grazer (sea urchin) preys in two South African islands. (A) Malgas, with a high density of adult lobsters. (B) Marcus, with a virtual absence of lobsters. The circles indicate relative biomasses (reproduced from Castilla JC, Branch GM, and Barkai A (1994) Exploitation of two critical predators: The gastropod *Concholepas concholepas* and the rock lobster *Jasus lalandii*. In: Siegfried WR (ed.) *Rocky Shores: Exploitation in Chile and South Africa*. Ecological Studies, vol. 103. pp. 101–130, with permission from Berlin: Springer-Verlag).

to be understood. Furthermore, nonanthropogenic impacts also need to be considered. Second, limited knowledge exists on the resilience properties of marine communities and ecological conclusions on linkages between marine ecosystems are based on preliminary data.

Humans and Ecosystem Engineer and Invasive Species

Ecosystem engineer species are species that directly or indirectly modulate the availability of resources (other than themselves) to other species by causing physical state changes in biotic or abiotic materials, and in so doing they modify, maintain, and/or create habitats (Jones *et al.*, 1994). Jones *et al.* distinguished (i) autogenic engineers, when the changes in the environment occurred via their own physical structure, living or dead tissues (e.g., coral reefs), and (ii) allogenic engineers, when they produced changes in the environment through the transformation of living or nonliving materials from one physical state to another via mechanical means (e.g., rabbits and burrows). In marine coastal communities, there are numerous autogenetic engineer species playing roles in the functioning of the community and ecosystem and creating the physical conditions for other species to exist (e.g., mussels, Lohse, 1993). In the Southern Hemisphere, rocky littoral zone tunicates of the genus *Pyura* play such a role (see Fielding *et al.*, 1994, for *P. stolonifera* in South Africa). These tunicates are also important as species

extracted for food and/or bait by recreational fishers, divers, and inter tidal food gatherers (for *Pyura praeputialis* in Australia, see Fairweather, 1991; for *P. praeputialis* in Antofagasta, northern Chile, see Castilla, 1998). The tunicates form dense intertidal and subtidal belt monocultures and attain collective cemented beds, creating microhabitats used by several dozen macroinvertebrates and algae. Fielding *et al.* identified 83 taxa of macroinvertebrates in intertidal and subtidal *Pyura stolonifera* beds around Durban, South Africa, whereas more than 100 taxa of macroinvertebrates and algae have been found in intertidal *P. praeputialis* beds in Antofagasta.

The *P. praeputialis* beds in Chile present a very restricted geographical distribution of only 60–70 km around Antofagasta Bay (Clarke *et al.*, 1999). According to a working hypothesis (J. Castilla, work in progress), the species might have been introduced recently to Antofagasta by ships or arrived on floating objects from Australia. In Antofagasta, a contrasting situation concerning species richness is found in sites with *P. praeputialis*, with more than 100 taxa in the *Pyura* beds, as opposed to sites without the tunicate, which have about one-third to one-fourth of the species. It is unknown how much ecological damage, if any, human extraction causes on the dynamics of *Pyura* populations or on species diversity at a local scale. However, preliminary information at Antofagasta indicates that following *Pyura* removals by waves, predators, or humans, the species reinvasades intertidal sites (the center of its distribution) within one year (J. Castilla, work in progress).

A higher rate of anthropogenic or nonanthropogenic removal of engineer species than the rate of recovery may be key to local species diversity.

Invasive species are displacing native species throughout the world. They are altering the physical nature of habitats (e.g., the effects of the Asian clam *Potamocorbula amurens* in the San Francisco Bay) and causing changes in food webs of economically important species (NRC, 1999). The best reported case is that of the Bay of San Francisco, in which ship activities (i.e., the elimination of ballast waters) have increased drastically the number of exotic species in the bay's benthic communities (Carlton, 1996). At the pelagic level the introduction in the bay of the zooplanktonic mysid *Acanthomysis* sp., which displaced another species of mysid, *Neomysis mercedis*, a major food item of the striped bass *Morone saxatilis*, is partly responsible for a severe decline in the bay's bass population (NRC, 1999). Furthermore, there are recent reports showing that the predator green crab *Carcinus maenas* has invaded the San Francisco Bay and is spreading through the coastal waters of California (Cohen and Carlton, 1998).

Mariculture

The intensive and extensive marine farming of fish, shellfish, and algae has a long history and is a controversial issue. For instance, mariculture production expectations have not been achieved (NRC, 1999) and adverse environmental effects, such as contamination of surface waters by fish wastes, eutrophication, spread of diseases, introduction of unwanted species, and deterioration of coastal habitats (e.g., mangroves in connection with shrimp farming in Asia and Latin America), have occurred (Chamberlain, 1997; Anderson, 1997). The introduction of exotic cultured species may be a serious and irreversible event to native ecosystems which merits careful consideration. For instance, oysters have been transported by man from country to country and there are several cases of the concomitant spread of pests (unwanted species) and diseases, even under strict import controls. The introduction of the American oyster *Cassostrea virginica* into English waters (late 1800s and 1939) brought in several exotic species, the worst being the American oyster drill *Urosalpinx cinerea* and the gastropod competitor *Crepidula fornicata* (Edwards, 1990). Critical epizootic disease events in the Gulf of St. Lawrence that caused serious oyster stock depletions were ascribed to the transplant of oysters in 1914 from New England to Canada (Edwards, 1990). No comprehensive ecological reports on the ecological effects of these species introductions and diseases on local species diversity or community functioning have been published.

The intensive farm-raising of high-value species, such as shrimp and salmon, is far from trouble-free. There are concerns about the increase in the deposition of particulates and accumulation of organic matter under salmon cages in intensive mariculture installations due to unwanted effects, such as anoxic conditions and the production of toxic gases (Beveridge, 1996). Coastal ecosystem destruction, nutrient loading, antibiotics wastes, accidental release of alien or genetically altered organisms, and disease spreading to native species are some of the threats to community and ecosystem functioning.

Human Overfishing, Diseases, and Trophic Cascades

Hughes (1994) and Jackson (1997) reported major ecological effects on coral reef communities as a consequence of the overexploitation of herbivorous fishes and a disease killing sea urchins. In Caribbean coral reefs, a chain of effects, starting with the overfishing of herbivorous fishes, appeared following category 5 hurricane Allen in 1980. Allen severely damaged coral reefs in Jamaica, but by 1983 there was evidence of their recuperation. Nevertheless, at that time a disease devastated the herbivorous populations of the sea urchin *Diadema antillarum*. The elimination of the herbivore guild caused dramatic food cascading effects, resulting in reefs overgrown by algae and the detention of their recuperation. Species diversity and community functioning severely changed: The coral cover was reduced from approximately 52% in 1977 to 3% in the early 1990s, and cover of macroalgae increased from approximately 3 to 92% (Hughes, 1994).

Pollution and Artificial Reefs

The cases exemplified are among the best known ecological situations in which human impacts and the function of communities or ecosystems, combined with changes in species diversity, have been observed or studied. However, there are additional examples showing anthropogenic negative, as well as positive, impacts on marine communities and ecosystems. Among negative impacts on marine species diversity and community functioning, the most conspicuous (not discussed here) is pollution (Castilla, 1996). Among positive impacts is the building of marine reefs for fishing enhancement and recreational purposes. Artificial habitats may locally enhance species diversity and resources and drive community structure toward alternative states (Buckley, 1982).

Nonanthropogenic Environmental Changes and Variability

Nonanthropogenic environmental changes and impacts on marine populations and communities have been well documented. For instance, Soutar and Isaacs (1974) reported large fluctuations in the density of scales of hake, anchovy, and sardines in sediment cores during the past 2000 years, well before fishing was a factor. Large-scale ocean climate changes, such as El Niño Southern Oscillation (ENSO) events, have dramatic negative (Arntz and Fahrbach, 1996) or positive (Castilla and Camus, 1992) impacts on fish, shellfish, and algae populations in the Southeastern Pacific. ENSO also causes multiple positive and negative oceanic, freshwater, and terrestrial impacts throughout the world.

Barry *et al.* (1995) reported changes between 1931 and 1933 and between 1994 and 1995 in species richness and evenness of intertidal invertebrates at a rocky intertidal transect in the Hopkins Marine Station, Monterey, California. They reported species' latitudinal range shifting northward, suggesting a consistency with predictions associated with anthropogenic-linked climate warming (but see alternative explanation by Denny and Paine, 1998). Nevertheless, it is debatable whether the current global warming trend, due partly to the build-up of several

greenhouse gases, is part of a long-term climatic trend. In any case, marine species with different geographical origins would have different responses to water temperature alterations (Castilla and Camus, 1992). Moreover, in the case of the oceans, water temperature modifications would be just one of the potential factors affecting the distribution of species. For instance, temperature effects on the turbulence of the ocean waters, and their association with wind stress, may have major implications for plankton dispersal. Also, the predicted north-south interhemispheric asymmetry, due to the thermal inertia in the south, must be considered before drawing firm conclusions on marine species latitudinal shifts (Bernal, 1994). Furthermore, since the ocean is affected simultaneously by several climate forces (including anthropogenic greenhouse effects), it is difficult to determine the real cause of any observed change, such as that in surface seawater temperature. Shifts in marine populations, community structure, and their functioning represent the integrated response of species assemblages to nonanthropogenic long-term climate changes superimposed on the effects of numerous short-term factors, including anthropogenic forcing.

Conclusions

This article discussed several marine examples in which direct anthropogenic and nonanthropogenic impacts (or combinations), such as species extraction and oceanic water temperature modifications, caused drastic ecological shifts on marine benthic intertidal, subtidal, and coastal-oceanic communities, and thereby modified species diversity and the functioning of associated communities. Interestingly, extreme conservation measures (e.g., the establishment of no-take areas) to protect species, habitat, community, or ecosystem may also cause drastic modifications in the functioning of marine communities and drive communities into alternative ecological states (Castilla *et al.*, 1994; Estes *et al.*, 1998; Castilla, 1999). This article highlighted that anthropogenic activities (e.g., mariculture) and impacts (e.g., overfishing) on different ecological categories of species (predator, keystone, engineer, invasive, and competitive dominant) translate into differential responses and functioning at the species diversity and community level. The unique ecological role played by humans and their apex keystone position in trophic webs were discussed.

Glossary

Abyssal plains Relatively flat areas of the ocean bottom below ~4000 m depth.

Benthos Bottom-living organisms, including those that reside on hard and soft bottom surfaces and others that reside between sediment grains.

Continental rise An area at the base of the continental slope between 3000 and 4000 m where the bottom slope is slight and sediments often accumulate.

Continental shelf A region of ocean bottom extending from the low water mark at the edge of continents to a depth (~200 m) at which the incline increases markedly and the continental slope begins.

Continental slope Ocean bottom extending from the edge of the continental shelf at an ~4° incline to a depth

(3000–10,000 m) at which the slope decreases and the continental rise begins.

Deposit feeders Organisms that feed primarily by ingesting organic material occurring on or between sediment grains.

Macrofauna Animals large enough to be retained on a 300- or 500-μm sieve.

Megafauna Animals those are sufficiently large to be identified from bottom photographs.

Meiofauna Animals small enough to pass through a 500-μm sieve but large enough to be retained on a 44- or 63-μm sieve.

Suspension feeders Organisms that feed primarily on particles of organic material suspended in the water above the bottom.

Benthos and the Benthic Environment

Depending on the specific habitat and species, different benthic (bottom-dwelling) organisms may reside just above the bottom but closely associated with it (hyperbenthos), on the sediment surface (epifauna), or among the sediment grains (infauna). Because sediments have limited permeability, very little oxygenation (penetration of millimeters) is typically achieved through diffusion. Greater oxygen penetration is achieved only when bottom currents mix sediments or, more commonly, when bioturbation (biological mixing of pore water and sediments by benthos) facilitates transfers of oxygenated water from the water column into the sediment pore water. Bioturbated sediments are usually oxygenated within the top few centimeters, although active bioturbation can lead to deeper pockets of penetration. Light does not penetrate well through sediments and most food is provided by phytoplankton detritus sinking from surface waters above, macrodetritus transported from coastal areas (e.g., kelps, seagrasses, and terrestrial plants), or from primary producers living attached to the sediment surface in shallow nearshore areas where light penetrates all the way to the bottom. Thus, most of the primary production or detritus in benthic systems concentrates near the sediment surface rather than within the sediments. This combination of limited food and oxygen penetration confines the vast majority of organisms to the upper few centimeters of sediment near the sediment–water interface. Smaller organisms that can tolerate low (hypoxia) or even no (anoxia) oxygen and larger organisms that maintain a burrow or appendage to the surface can live deeper, but even then distributions are generally limited to 10–20 cm or less (see Gray and Elliot, 2009).

As in other environments, feeding modes include herbivores, predators, scavengers, parasites, and omnivores. However, most organisms that reside in marine sediments are classified either as deposit feeders or as suspension feeders, and some species are capable of either feeding mode. Deposit

feeders ingest particles associated with sediments or, in many cases, they ingest the sediment particles themselves and strip off nutrition in the form of detritus associated with the sediment grains and also associated microbes. In shallow areas, benthic algae (diatoms) may provide a food source for some deposit-feeding species. Deposit feeders are important to sediment geochemistry because, as they move through the sediments, they facilitate pore water and sediment grain movement. Suspension feeders remove particles such as phytoplankton and detritus from the water column. Because they rely on suspended particles, suspension feeders tend to be most abundant in energetic environments and absent where weak currents reduce horizontal flux of food particles. Differences in the physical energetics of an environment also influence the stability of the benthic habitat and the organisms that live there. Quiescent areas usually have fine-grained sediments that are relatively stable except where storms pass through. High-energy environments are more dynamic in terms of sediment movements; fine-grained sediments are usually absent and ambient flow conditions often move around the coarse-grained sands that remain. Not surprisingly, shallow coastal environments are the most dynamic, whereas much of the deep sea is relatively quiescent because wave energy rarely penetrates beyond 50–60 m with sufficient strength to move sediment grains.

For reasons of sampling and taxonomic practicality, benthic researchers routinely focus on just one of several size groupings. Megafauna are defined as organisms sufficiently large to be identified in bottom photographs and include flatfish, crabs, and scallops. Macrofauna are defined as those retained on a 300- or 500-μm sieve (standards vary). This size grouping includes polychaete annelids, crustaceans, bivalves, and many other phyla (Figure 1). Meiofauna refers to organisms that pass through a 300- or 500-μm sieve but are retained on a 44- or 63-μm sieve and include nematodes, foraminiferans, tiny crustaceans, and many others (Figure 2). Microorganisms include living organisms that pass through a 44- or 63-μm sieve

Figure 1 Typical sedimentary macrofauna, including amphipod crustaceans (a and b), echinoderms (c), bivalve (d and e), and gastropod (f) mollusks and annelid polychaetes (g–i). Magnification in the photos varies but individuals range from approximately 1 to 10 mm in length (photographs by P. Ramey).

Figure 2 Typical sedimentary meiofauna, including harpacticoid crustaceans (a), nematodes (b), and foraminiferans (c). Magnification in photos varies but individuals range in size from approximately 100 to 300 μm (photographs by P. Ramey).

and include bacteria and protists. These size groupings are not absolute in that the larval or juvenile stages of one group may be comparable in size with individuals from a smaller group, but this division of organisms is necessary because of sampling logistics. The sample size and equipment appropriate for enumerating megafauna, for example, is inappropriate for sampling meiofauna that are orders of magnitude more abundant and substantially smaller. Moreover, the taxonomic challenges even within each of these size groupings are considerable, and synthesis across groups is therefore rare in a single study.

These groups of organisms do not operate independently of one another. Megafauna prey on infauna, and macrofauna prey on meiofauna. There is also evidence that meiofauna prey on juvenile macrofauna. Microbes form an important dietary component for many meiofaunal and macrofaunal taxa, and macrofaunal bioturbation impacts microbial composition because it oxygenates sediments and thereby regulates the relative importance of aerobic versus anaerobic bacterial activity. Microbes also initiate breakdown of food material that would otherwise be undigestible by metazoans and play a

major role in cycling of organic matter. Thus, there is considerable interaction between these groups of organisms.

Many factors are thought to influence the spatial distribution of benthic sedimentary organisms, including sediment type, productivity, temperature, salinity, pressure, depth, oxygen, sediment stability, air exposure, current speeds and wave action, and biological interaction with other species. A more complete treatment of benthic organisms is given in Gray and Elliott (2009).

Marine Sedimentary Habitats

Oceans range in depth from intertidal habitats to ocean trenches at 10,000 m depth (Figure 3). Light can penetrate to 1000 m in the clearest oceanic waters, but in coastal waters penetration may be limited to from 200 m to only a few meters. Like most ecosystems, marine sedimentary communities are fueled by photosynthesis, and because many marine sediments occur below photosynthetic depths they rely on phytoplankton sinking from surface waters above and macrophyte detritus transported from nearshore environments. Not surprisingly, water depth is a major variable in categorizing marine sedimentary habitats.

Intertidal Habitats

The shallowest sedimentary habitats are those that occur at the land–sea interface. They include habitat with emergent

vegetation such as mangroves and salt marshes as well as sandflats and mudflats without emergent vegetation that may or may not include diatom mats (Table 1). Mangroves and salt marshes occur intertidally, and as such they experience wide ranges of salinity and temperature. They are also extremely productive, with abundant organic matter in the form of decaying vegetation. The productivity of these systems promotes extremely high bacterial respiration and sediments are often hypoxic or even anoxic except at the sediment–water interface. The organic matter produced by vascular plants is also relatively refractory and difficult for most species to digest. In combination with oxygen limitation and tidal exposure, this refractory material contributes to the low diversity of organisms residing in the sediments. Unvegetated sandflats and mudflats tend to be much lower in productivity unless they are immediately adjacent to vegetated areas, and their diversities are slightly elevated. Nonetheless, intertidal areas experience high variation in environmental variables and are characterized by a low-diversity fauna consisting of organisms able to cope with this variability (see Levin *et al.*, 2001).

Subtidal Habitats

At depths below low tide, species diversity increases relative to that of intertidal systems. In the shallowest subtidal habitats, vegetation in the form of seagrass and kelp may occur, and some shallow sediments may be covered in diatom mats. However, all these plant forms are confined to depths of tens of meters or less, and most subtidal sedimentary habitats rely

Figure 3 Schematic diagram of the depth zones of the oceans. Dark area indicates the ocean bottom. The distances and depths given are only examples of a range or values observed throughout the world. The horizontal axis is greatly exaggerated in size relative to the vertical axis. See text for more detailed explanation of depth zones.

Table 1 Summary of sedimentary habitats, local diversity, ecosystem services provided, and current threats^a

<i>Sedimentary habitat</i>	<i>Diversity</i>	<i>Ecosystem services</i>	<i>Current threats</i>
Salt marshes	Low	Nutrient cycling, critical habitat, shoreline stability, filtration, productivity, and pollutant cycling	Habitat destruction, pollution, and global climate change
Mangroves	Low	Nutrient cycling, critical habitat, shoreline stability, filtration, productivity, and pollutant cycling	Habitat destruction, pollution, global climate change, and exotic species
Sandflats	Low to modest	Nutrient cycling, filtration, and productivity	Habitat destruction, pollution, and exotic species
Mudflats	Low to modest	Nutrient cycling, productivity, and pollutant cycling	Habitat destruction, pollution, and exotic species
Estuaries	Low	Nutrient cycling, critical habitat, filtration, productivity, and pollutant cycling	Habitat destruction, pollution, global climate change, and exotic species
Coral reef sediments	Very high	Nutrient cycling and productivity	Habitat destruction, pollution, and fishing
Continental shelf	Modest to very high	Nutrient cycling, critical habitat, filtration, productivity, and pollutant cycling	Habitat destruction, pollution, fishing, and exotic species
Continental slope	Medium to very high	Productivity and nutrient cycling (global)	Habitat destruction and fishing
Abyssal plains	High to very high	Nutrient, element cycling (global)	—
Hydrothermal vent sediments	Low	Nutrient, element cycling (global)	Mineral extraction from adjacent vents
Deep ocean trenches	Low	?	—

^aThe table summarizes generalities for which there are exceptions. In the case of global climate change, the large-scale circulation changes, warming and acidification, predicted in many models would threaten all habitats, and only more immediate impacts are included here.

on sinking plant material as the base of their food chain. Sedimentary environments may range from gravel to fine clays. Fine-grained sediments characterize low-energy environments and coarse-grained sediments characterize many high-energy areas. The latter are often dynamic environments, where bottom flow frequently moves sediments. A wide variety of organisms inhabit the sediments that cover much of the continental shelves. The shallower portions of these environments (up to tens of meters) can experience strong seasonality in productivity and temperature, and salinity may vary considerably where offshore runoff is significant (e.g., estuaries). Within these systems, greater environmental variability and lower diversity go hand in hand. With increased depth, the variability in salinity and temperature is generally reduced, although productivity can still be seasonal. Continental shelf areas are large, productive areas of the oceans and support the majority of marine commercial fisheries.

Deep-Sea Habitats

The deep sea, defined here as habitats beyond the edge of the continental shelf at ~200 m, encompasses continental slopes, continental rises, abyssal plains, midocean ridges, and trenches. Although the sediments that cover the bottom can vary in grain size composition, environmental variability is considerably reduced. Temperatures are largely invariant, salinity does not change, and sediments are rarely moved around other than by bioturbation. Depending on the region, productivity is generally less seasonal than in shallow water, and most deep-sea benthic environments have much less productivity entering the system than their shallow-water counterparts. Because these environments exceed depths of light penetration, productivity consists of whatever material sinks through the thousands of meters of water column to the bottom. As a result of this reduced productivity, numbers of

organisms are very low and individuals are relatively small; surprisingly, species diversity is quite high. A very notable exception to low productivity in the deep sea is hydrothermal vents and seeps, for which chemoautotrophic bacteria provide the basis for an extraordinarily productive localized community.

Not all deep-sea communities are diverse. Because hydrothermal vent environments are characterized by fluids rich in compounds such as hydrogen sulfide and heavy metals, most species are unable to tolerate these toxic compounds and species diversity is quite low. Deep-sea trenches are subject to mud slumping and poor circulation. Not surprisingly, species diversity is also low. Upwelling regions are also generally low in diversity, likely because large amounts of organic matter accumulate on the ocean floor and decompose, leading to hypoxia. A few deep-sea areas are subject to intensive “storms,” in which currents become intense and resuspend sediments. Evidence suggests that macrofaunal diversity is depressed in such areas, but surprisingly meiofaunal diversity is not. Presumably, the meiofauna are able to cope with the disturbance more effectively than are the macrofauna.

Global Estimates of Species Numbers

Several attempts have been made to estimate the total number of species that live in the ocean. The Danish marine scientist Thorson estimated in the early 1970s that 100,000 species would eventually be described from the marine environment, and until recently this was the ballpark figure most thought appropriate. In the late 1960s, deep-sea biologists Sanders and Hessler documented that the deep sea was not the low-diversity habitat that many had previously thought and could contain a significant portion of global marine species diversity (Hessler and Sanders, 1967; Sanders and Hessler, 1969). The debate on species estimates heated up considerably when

Grassle and Maciolek (1992) published data from a collection of samples along a 176-m-long depth contour along the east coast of the USA, constituting the most extensive quantitative data set ever assembled for a single area of the deep sea. Based on the rate that species were added with increased area sampled, and the total area of the deep sea, they extrapolated to 10 million macrofaunal species. May (1992) pointed out that approximately half of the species in their study were new to science, and one could extrapolate from known to unknown species using a similar ratio. Given that approximately 250,000 marine species have already been described, May's (1992) extrapolation suggests ~500,000 total species living in the oceans. Other work from the Pacific (Poore and Wilson, 1993) suggests that only one in 20 species has been described for that area of the deep sea, in which case May's approach would yield ~5 million species.

Although most of the discussions on species number have centered on macrofauna, the lesser known meiofauna and especially the microbes represent a potentially massive pool of undocumented diversity. But because so little is known about how widely distributed individual species may be, extrapolating numbers is even more tenuous and controversial than for macrofauna (Lambshead, 1993; Lambshead and Boucher, 2003).

Clearly, more data are needed to improve estimates of global species numbers. Current estimates for metazoans range from 500,000 to 100 million species, but vast areas of the ocean and some taxonomic groups remain unsampled or poorly sampled. The South Pacific and tropical latitudes are among the least known areas. Even many shallow environments remain poorly known, and recent evidence suggests that some of these areas may be very species rich. For example, a United States National Research Council (1992) study summarized surveys that found two-thirds of the polychaetes in Hawaiian coral reef sediments were previously undescribed; even Georges Bank, a relatively well-studied area, was found to have only two-thirds of its polychaete species previously described. The situation is even more severe in deep-sea areas and for meiofaunal taxa such as nematodes and copepods, for which proportions of known species can sometimes be less than 5–20% of total species present (Ebbe *et al.*, 2010). Even for taxa thought to be well known, there is increasing evidence based on genetic data that 'cosmopolitan taxa' are often species complexes that are difficult to distinguish based on morphological characters. Regardless of which projection of total species number is appropriate, there remains a huge amount of undescribed species diversity in marine sediments. New approaches such as genetic barcoding should expedite discovery, but the numbers of scientists working on the problem are few relative to the size of the problem.

Global Patterns of Biodiversity

The historical perception of the deep sea as an azoic or species-poor environment changed markedly with a series of papers (Hessler and Sanders, 1967; Sanders and Hessler, 1969) that report on data collected along a transect running from Martha's Vineyard, Massachusetts, to Bermuda, and demonstrated that diversity in deep-sea sediments exceeded that in most

shallow areas and rivaled that observed in shallow tropical areas. These findings contradicted a previous notion that diversity would generally decrease with depth. Rex (1983) followed up this work with extensive analysis of large-scale pattern with depth in the North Atlantic and found that diversity is highest at intermediate depths. Diversity in shallow water is low in estuaries and seasonal shallow areas, is somewhat higher on the continental shelf, increases down the continental slope, and peaks on the lower slope. At greater depths it declines again. Other workers have observed a similar pattern for other taxa, although the exact depth of the diversity peak varies among taxa and also among locations (Menot *et al.*, 2010). Moreover, diversity in the abyssal plains of the Pacific appears to exceed that observed at shallower depths, suggesting that a parabolic diversity–depth pattern is not universal. The generality of lower diversity in shallow water was questioned by Gray *et al.* (1997), who presented convincing data that the local diversity of sedimentary fauna of Bass Strait, Australia, (11–51 m deep) may rival or exceed that of the deep sea. The pattern observed by Rex and others has been based largely on data from the North Atlantic, and Gray's findings emphasize the fact that patterns described from one area may not be easily extrapolated globally.

Many studies have documented latitudinal gradients in shallow-water benthic diversity, with decreasing diversity toward the poles. In the deep sea, the existence of such a trend is the subject of debate. The pattern has been proposed for North Atlantic deep-sea macrofauna (Rex *et al.*, 1993), but isopod data from the South Pacific (Poore and Wilson, 1993, 1992) do not indicate such a pattern and nor do some nematode data for the North Atlantic (Lambshead *et al.*, 2003).

The inconsistency of conclusions regarding global patterns in diversity indicates a need for more complete sampling coverage with latitude and depth. Improved coverage would allow more effective comparison of different oceans and reduce the impact of 'noise' added by regional differences in variables such as productivity that are bound to obscure any global patterns. Within this coverage, areas that have been poorly sampled historically, such as tropical sediments and the Southern Hemisphere, must be emphasized to reduce the North Atlantic bias. An additional problem with these large-scale comparisons is that most studies focus on just one of the size groupings of organisms and generally use different sorts of sampling techniques. For example, one must ask whether differences described in large-scale patterns in different taxa and ocean basins reflect differences in biology or sampling coverage. Studies that are more comprehensive in taxonomic and geographic coverage are necessary to resolve these debates.

Regulation of Diversity

Shallow Water

Our understanding of diversity regulation in marine systems is limited. In environments with extremes of temperature (e.g., intertidal sediments), salinity (e.g., estuaries), geochemistry

(e.g., sediments near hydrothermal venting), or oxygen (e.g., eutrophied coastline, mangrove sediments, and fjords with poor circulation), there are obvious physiological limitations for many species that allow only the most robust species to exist. The same may be said for physically disturbed environments such as low-diversity sandflats. Similarly, the reduced diversity in highly seasonal environments presumably results from relatively few organisms able to cope with the variability in the physical environment. However, beyond these extreme habitats, obvious conclusions on diversity regulation are few.

Historical events and modern conditions both play major roles in determining global diversity patterns. Certainly, the evolutionary history of a region must be considered. Jablonski's (1993) analysis of fossil invertebrates suggests that the tropics provide evolutionary novelty, and thus contribute to the higher diversity noted in tropical latitudes. Glaciation effects played a well-known role in establishing current marine patterns. For example, the reduced diversity observed in Arctic relative to Antarctic fauna (a pattern questioned in some recent studies – see Gradinger *et al.*, 2010) likely relates to extinctions during Arctic glaciation and the slow reestablishment of the Arctic community. Thus, historical events set the stage for current ecological processes, which may subsequently play a role. In terms of modern conditions, the high level of total energy input in the tropics has been proposed to explain shallow-water mollusk diversity gradients, and the high degree of seasonality with increasing latitude may be a factor that depresses diversity.

The role that ecological interactions play in sedimentary diversity is less well understood. In shallow-water experiments, the exclusion of predators seems to enhance diversity (see Peterson, 1978). This finding is the direct opposite of Paine's (1966) classic findings in rocky intertidal communities and suggests that it is inappropriate to generalize from relatively well-studied rocky intertidal systems to the less understood sedimentary environment. Whether generalizations regarding predators depressing diversity can be extended to the deep sea remains to be tested. There is a dearth of experiments linking diversity in the water column to sedimentary faunal diversity and little data on how predator diversity might impact benthic diversity. One might predict, for example, that increased diversity in food sources (e.g., phytoplankton) might lead to enhanced diversity in the infauna that feed on those food sources. Increased diversity of predators might also allow tighter species packing in an environment.

Deep Sea

There has been considerable debate on how the deep-sea environment, which appears so physically homogeneous, is able to support such a broad array of species. Sanders, who played a pivotal role in recognizing the high diversity of marine systems, suggested that the high level of stability over evolutionary time in the deep sea has allowed greater specialization and niche diversification. If this were the full explanation, then diversity should be highest on abyssal plains; the depth patterns described in the previous section on patterns do not consistently support this notion though newer

data suggest abyssal plains may be more diverse than previously thought. There is also little evidence of niche specialization in deep-sea organisms. Most species appear to be relatively nonselective deposit feeders. In the early 1970s, several contrasting theories were put forward. First, cropping by predators could prevent competitive equilibria from being attained by infauna. If this were the case, however, then fast growth, early reproductive maturity, and an age structure dominated by young individuals might be expected, but this is not a pattern typical for the deep sea. Moreover, evidence from shallow water suggests that predators decrease sedimentary diversity. In any case, the role that predators may play in maintaining deep-sea diversity remains largely unknown. A contrasting theory held that small patches may form disequilibria habitats that promote certain species. Tests of this patch mosaic model have included sampling of natural patches and creation of experimental patches. Both approaches have yielded a similar result: The species that occur in many patch types are usually rare or absent from background sediments, although diversity in patches is usually reduced. Such a pattern is consistent with the patch mosaic model, but experiments so far have demonstrated that patches promote only a modest number of species. Whether it is necessary to sample more patch types, or whether other explanation needs to be invoked, remains unclear.

The large area of the deep sea almost certainly impacts its species richness in that species richness of most environments increases with area. However, the vast rolling plains of the deep sea add less habitat heterogeneity than other species-rich habitats, such as tropical rain forests or coral reefs. Given that abyssal plains are the largest deep-sea habitat in area, the parabolic diversity–depth relationship described earlier is also inconsistent with a simple species–area relationship.

Huston's (1979) intermediate disturbance hypothesis is another explanation for the high diversity of deep-sea systems. The idea is that, at one end of the spectrum, high levels of disturbance depress diversity by eliminating sensitive species. At the other end of the spectrum, very benign habitats allow superior competitors to eliminate weaker species and thus depress diversity. Highest diversity would then be expected in habitats with levels of disturbance that prevent competitive dominants from taking over but not so frequent and harsh that few species can cope. The midslope peak in diversity described earlier (*see* Global Patterns) is consistent with this hypothesis but does not offer an explicit test of the hypothesis. Most disturbed deep-sea environments, such as hydrothermal vents, low-oxygen areas, environments with benthic storms, and slumping areas, have reduced diversity. However, such extreme examples are far from conclusive in drawing comprehensive generalities.

Efforts to understand regulation of biodiversity in the deep sea have been hampered by the considerable logistical challenges of deploying and recovering experiments in deep, oceanic environments. In shallow-water environments, diversity regulation has received considerably less attention, and there is a pressing need to move some of the deep-sea framework and experimental effort into shallow water where logistics are simplified and outcomes are bound to produce interesting comparisons with the deep sea. Our understanding of diversity maintenance in sedimentary systems is generally

very poor, and we are unable to predict, for example, whether loss of pelagic diversity will impact benthic diversity. The problem is that humans impact diversity of marine benthic organisms in many areas through fishing, habitat destruction and modification, pollution, exotic species introductions, and global climate change, but there is often little idea on how different components of the ecosystem will be affected.

Ecosystem Services and Sedimentary Diversity

Although the huge fraction of the Earth's surface covered by marine sediments and the large numbers of species residing within sediments provide strong motivation to understand the pattern and regulation of benthic diversity, there are also good ecological motivators. The oceans provide a variety of ecosystem services (Figure 4), and although we understand little about the role that biodiversity plays in maintaining these services there is very clear evidence that benthic species play critical roles. There is a very real chance that ongoing changes in sedimentary biodiversity will result in loss of ecosystem services.

Nutrient Cycling

Benthic marine organisms play a critical role in global cycles of nitrogen, sulfur, and carbon (Giblin *et al.*, 1995; Snelgrove *et al.*, 1997). As organic material sinks to the sediment surface, it carries with it organic carbon and nitrogen. This material may be directly ingested by benthic organisms or microbes may colonize it. In areas with high sedimentation rates or low densities of organisms, there may be substantial burial loss of this material, but most is consumed or decomposed. Even the

organic material that passes through organisms undigested will be colonized and broken down by microbes. Organisms that ingest the material respire, are preyed on, or die and decompose in the sediment. Depending on how decomposition and digestion occur, nitrogen may be released as ammonia, nitrite, nitrate, or nitrogen gas that diffuses or is physically mixed into the water column above. In coastal sediments, this cycle is a critical part of regenerating the dissolved nitrogenous compounds that are essential for primary producers; without this regeneration the cycle would end and primary production would cease. Carbon is cycled in a similar way. Material sinks to the bottom and may eventually be buried (e.g., fossil fuels) or it may be decomposed into carbon dioxide or other carbon compounds. The relative rates at which carbon is buried, tied up in living organisms, or respired to carbon dioxide are closely tied to microbial activity and thus to the animals that influence microbial activity through feeding and oxidation of sediments. As a result, benthic organisms play a key role in global carbon budgets. Sulfur cycling through marine sediments is also dependent on sediment oxygenation and therefore bacterial activity. Whether sulfur is buried and stored in sediments or recycled is determined in part by metazoan and microbial activity.

Pollutant Cycling

Because benthic organisms move around and ingest particles, and may themselves be ingested by predators, they can greatly impact the burial fate and mobility of pollutants. As sediment particles are bioturbated, so are any pollutants linked to them. As a result, benthic organisms can dilute pollutants at the sediment–water interface by mixing them downward. By the same process, the continual remixing of sediments by infauna

Figure 4 Schematic representation of key ecosystem services associated with sedimentary organisms. Arrows indicate transfer of material between the water column of the ocean and the sediment.

may increase burial time of pollutants that might otherwise be buried more quickly by sedimentation. Bioturbation also tends to destabilize sediments and increase the likelihood that they will be resuspended. Some sedimentary organisms can also stabilize sediments by excreting mucous (e.g., bacterial mats) or creating tubes that they inhabit. Benthos may also increase effective grain size by repackaging grains as fecal pellets. All these processes impact whether sediments are likely to be resuspended or not. Infauna that ingest pollutants may also provide a conduit up the food chain if they concentrate the pollutant in their tissues. For example, fish that feed on polychaetes with high levels of a heavy metal may also have high concentrations of that metal. Finally, benthic organisms have some capacity to break down pollutants. Microbes in particular may have the capacity to break down some toxic compounds and render them harmless.

Sediment and Shoreline Stability

Because benthos can destabilize (bioturbation) and stabilize (microbial mats, mucous excretion, and tube building) sediments, they can have a major impact on sediment transport and coastal geology. Mucous excretion, for example, binds sediment grains together and therefore increases the amount of energy required to move sediments. However, as some organisms produce products that bind sediment grains together, other organisms move among the sediment grains, breaking apart binding structures, increasing the water content, and increasing the likelihood of resuspension.

The vegetation in seagrass beds, mangroves, and salt marshes acts as flow baffles and therefore traps fine sediments, a process that is further aided by root structures that add further stability. The presence of these plants protects the shoreline and results in accretion rather than erosion. Indeed, rapid shoreline growth has been documented in areas with mangroves and marshes, where land is extended seaward on scales of kilometers more than timescales of hundreds to thousands of years.

Filtration

The benthos can also impact water clarity in coastal areas. The sediment-trapping capacity of emergent vegetation reduces sedimentation to the coastal waters beyond the marsh, mangrove, or seagrass bed. In tropical areas, for example, mangroves and seagrasses can trap sediments that might otherwise be transported onto coral reefs, where the suspended sediment would reduce water clarity and productivity and potentially smother corals. In temperate latitudes, marshes are well known not only for their ability to trap sediments but also for their capacity to take up excess nutrients. Agricultural runoff to the coastal environment can result in eutrophication, but the presence of salt marshes can significantly offset this problem and provide a natural water filtration system. Mangroves have a similar capacity.

Suspension-feeding benthos can also impact water clarity by filtering out suspended particles. The reduction of oysters in estuaries along the east coast of the US through overfishing, destruction of oyster reef habitat, and disease has resulted in a

marked decrease in water clarity. Impacts of this magnitude are generally confined to shallow nearshore habitats with very high densities of suspension feeders, but the effect is nonetheless important.

Secondary Production

Benthic megafauna and macrofauna provide an important source of secondary production. Some of this production, such as clams, scallops, shrimp, and crab, is directly consumed by humans and forms the basis of important commercial fisheries. However, even groups such as the polychaetes, which have no obvious economic importance, form an important food source for benthic-feeding fishes and crustaceans. Because sinking organic material collects on the bottom, the secondary production in the benthos can often be considerably higher than that in the water column above.

Linking Biodiversity and Ecosystem Services

Although benthic organisms inarguably provide key ecosystem services (Snelgrove, 1998), there is little evidence that species diversity *per se* is important in maintaining these services. This deficiency does not necessarily mean that species diversity is unimportant but rather that it has not been studied. In virtually all the categories listed, there is a particular functional group that is critical to the service, but in most cases there are more than one species of a particular functional group in a given habitat. For example, deposit feeders are the major bioturbators in marine sediments, and bioturbation has major impacts on nutrient cycling, pollutant burial and mobilization, and sediment stability. However, most sediments that contain deposit-feeding organisms will contain multiple species. At least superficially, it appears that different deposit feeders often do the same sorts of things, although there are species that feed on particular grain sizes and at particular depth horizons in the sediment. What is not known is whether those species that remain after others are eliminated can provide the same ecosystem services as the more diverse community. Will the removal of a given species result in fewer total numbers of deposit feeders or will other species increase in number or activity to compensate? Elmgren and Hill (1997) provide evidence from the Baltic Sea that complete removal of a functional group (in this case suspension feeders) will indeed fundamentally impact trophic linkages. Similarly Danovaro *et al.* (2008) found a positive relationship between diversity of different functional groups of meiofaunal nematodes and carbon production in deep-sea sediments. Further experiments to test these ideas and that span a wide range of habitats are sorely needed. It is clear that changes in functional groups will alter the way in which ecosystem services are carried out, but any linkage between regional or local biodiversity and ecosystem services in marine systems remains to be demonstrated.

In some instances, there are likely to be keystone species that provide services disproportionate to their abundance. Clearly, the loss of these species will have a major impact. In other instances, there may be only a single species providing a service so that loss of that species will have an easily predicted

outcome. Seagrasses and mangroves, for example, are often composed of only one or two species of emergent plant in a given area, and the loss of that species will have a clear effect. The loss of seagrasses to disease in Europe earlier this century had very clear effects on coastal sediments and shoreline erosion. Similarly, the loss of oysters (*see* Ecosystem Services and Sedimentary Diversity) had an obvious impact. Unfortunately, we are not always able to predict keystone species and we are even less able to predict the cumulative impacts of multiple species that belong to a given functional group.

Threats to Sedimentary Diversity

Documented extinctions in the marine environment are relatively few, and many of these are birds or mammals. However, there are certainly biodiversity losses occurring in the sedimentary fauna. Particularly in coastal areas, where human impacts have been most severe, large areas of habitat are being damaged or lost (Norse, 1993; National Research Council, 1995). At the very least, genetic diversity is disappearing with these habitats. Species that live in coastal habitats are often adapted to local conditions and may therefore have a specific tolerance to variables such as salinity and temperature. Once this gene pool has been lost, there is no guarantee that conspecifics from other areas will be able to invade that specialized environment. There is also increasing evidence that a significant portion of sedimentary diversity is undescribed and may subsequently be lost without our realizing it even existed. With these losses, changes in ecosystem services could also be missed or misinterpreted.

It is possible to generalize that with increasing proximity to the shoreline, and therefore to human populations, the number and magnitude of threats to sedimentary diversity increase (Figure 5). Thus, salt marsh and mangrove habitats

are being reduced at a rapid rate, continental shelf habitat is being damaged in many although not all areas, and deep-sea habitats are currently being impacted in mostly isolated instances. The types of impacts are far from uniform between systems.

Fishing Impacts

Most of the major marine fisheries in the world occur on continental shelf areas, and they can impact sedimentary habitats in several different ways (*see* review of Dayton *et al.*, 1995). Among the most destructive forms of fishing are dredges and trawls that are dragged across the bottom to collect benthic fishes and invertebrates (Watling and Norse, 1998). These types of fishing gear are often heavy and specifically designed to dig into sediments, and in doing so they alter the sediment composition and geochemistry, damage infaunal organisms, and destroy any benthic epifauna and plants and the habitat they create for other species, including some commercial fish. Many fisheries are also notoriously nonselective, and subsequently remove (as by-catch) large numbers of species other than those intended. By-catch, which is often 50–80% of the total catch, is often thrown overboard; most organisms discarded in this manner will be unable to recover, and pockets of decaying organisms then create localized areas that are similar to eutrophied habitat.

Fisheries also tend to remove top predators, and because these are large and abundant taxa they are species that have a major impact on their ecosystem. There are well-documented cases of shifts in species composition and trophic mode that occur as dominant predators are fished out (Botsford *et al.*, 1979).

In general, fisheries tend to reduce benthic diversity and homogenize habitat, although the specific means by which diversity loss occurs is only well documented in the case of

Figure 5 Schematic representation of major threats to sedimentary organisms and the services they provide.

physical destruction of habitat. Indirect effects, such as predator removal, require additional study.

Habitat Destruction, Degradation, and Shoreline Modification

Fishing activities are certainly the greatest source of degradation of bottom habitat beyond the immediate coastline, but coastal development has resulted in considerable reclamation of intertidal habitat ranging from salt marshes to mangroves and mudflats. A significant portion of The Netherlands and Boston's Logan Airport are just two examples in which shoreline has been engineered by filling or erecting dykes to allow development at the land-sea interface. Globally, large areas of marsh habitat have been modified to allow building, and large areas of tropical mangroves have been eliminated to allow development of shrimp aquaculture farms. Clearly, the loss of large areas of habitat changes local species composition and likely reduces genetic diversity of individual species. Extinctions are likely occurring in some areas.

Pollution and Eutrophication

The large human populations and industries that occur along coastlines throughout much of the world create problems of eutrophication, pollution, and habitat degradation (Pearson and Rosenberg, 1978). Eutrophication occurs when excess nutrients are supplied to coastal water from agricultural runoff and sewage. Phytoplankton and shallow vegetation respond to increased nutrients by growing, and as they die and sink to the bottom microbial decomposition occurs. Where large amounts of organic matter are available, microbial respiration exceeds photosynthetic production of oxygen and sediments, and bottom waters may become hypoxic or anoxic.

Pollutants are also problematic in coastal environments. Industrial and storm drain runoff deliver heavy metals, hydrocarbons, synthetic compounds (polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT), dioxin, etc.) and countless other toxic compounds to sedimentary communities. Some of these compounds result in increased respiration, reduced reproductive output, and countless other physiological responses that may ultimately lead to death. Alternatively, the physiological stress caused by contaminants may weaken an organism and increase its susceptibility to disease. Transfer of contaminants may occur by diffusion, ingestion of contaminated particles, or feeding on contaminated organisms.

Problems of eutrophication and pollution are most intense in industrialized and densely populated coastal areas where circulation with the open ocean is limited. Thus, partially enclosed estuaries and harbors provide no mechanism for rapid dilution and removal of contaminants. Not surprisingly, the deep ocean is largely buffered from most of these impacts by the size of the continental shelf, given that most contaminants arrive as runoff of some sort from land or rivers. Nitrogenous compounds may also be delivered over broader distances by atmospheric deposition. For the coastal areas that are impacted by eutrophication and pollution, many benthic species are unable to survive under these conditions, and

bottom habitats become low in diversity and dominated by weedy species that thrive under such conditions.

Exotic Species Introductions

Within recent years, there has been increasing concern regarding the impact that introduction of nonnative (exotic) species can have on benthic communities (Carlton, 1985). Although many people assume that the oceans are open systems and lack barriers to dispersal, there are actually many discontinuities in temperature, land barriers, depth, and ocean currents that limit the dispersal of reproductive propagules from different areas of the world. Historically, ships have provided a mechanism by which exotic species are transported to nonnative habitat. In the case of hard-substrate fauna, fouling of ship hulls allows adults to cross deep ocean basins that they could not otherwise cross because of a lack of suitable shallow habitat. However, for sedimentary invaders, ship ballast water is the main culprit. A tanker may take on large volumes of ballast water in one port, sail to a new port, and dump the ballast water before loading goods. The dumped ballast water may contain adults and reproductive propagules that have been carried through unfavorable open-ocean habitat.

In recent years, the increasing interest in developing marine aquaculture has also helped spread nonnative species. Nonnative species are transported into new environments in which adults or reproductive propagules can escape into the wild, invade nonnative habitat, and displace native forms. An additional problem is that parasites and pathogens can be transported along with species imported for aquaculture, creating additional problems. Another transfer mechanism that is less common, but embarrassing, is the transport of organisms throughout the world for scientific study; although scientists are usually conscientious about preventing individuals or reproductive propagules from escaping into the natural environment, there are instances of accidental release.

In many instances, nonnative individuals will not successfully colonize the new environment, but particularly when conditions are stressful for native organisms (e.g., pollution and unusually low salinity or high temperatures), the exotic species may not only invade but also displace native organisms. When displacement occurs, even after conditions return to normal, the invasive species may remain the dominant taxon. San Francisco Bay and Long Island Sound are two good examples in which it is well documented that many of the dominant species today are nonnative. In some instances, the exotic and native species may be able to coexist, resulting in slightly higher biodiversity, but the complexity of species interactions can sometimes result in elimination of native species. In other words, the introduction of nonnative species is a very dangerous and unpredictable disturbance whose potential impacts are only beginning to be understood.

Global Climate Change

Perhaps the least easily predicted impact of human activity on sedimentary biodiversity is the long-term effects of global climate change (Smith *et al.*, 2000). In a simplistic sense,

species distributions might be expected to shift toward the poles to compensate for warming of the oceans. However, community response is likely to be far more complicated. Because the habitat of a given species is more complex than just temperature, it will often not be possible to simply shift distributions because suitable sediment and geomorphic features (e.g., productive banks) may be unavailable. As sea level rises, intertidal communities will not simply encroach landward because in populated areas such encroachment will be prevented to preserve expensive coastal development. Moreover, models of global warming predict potential circulation changes in the oceans, and if this indeed happens then a whole suite of ecological processes ranging from primary productivity to dispersal of reproductive propagules will be impacted. It is very likely that coastal habitats and species will be lost if significant ocean warming occurs, and it is possible that deep areas will also be impacted if these changes alter large-scale circulation patterns.

Summary

Although it is likely that ocean sediments contain in excess of 500,000 species, little is known of how this diversity is maintained and how loss of biodiversity may impact the ecosystem services that benthos provide. It is critical that benthic ecologists working in sedimentary habitats ride the current wave of interest in biodiversity to improve on these deficiencies in our knowledge. Marine sedimentary systems are widespread, rich in biodiversity, and ecologically important in terms of the processes that occur within them. It is therefore reasonable to expect exciting discoveries regarding biodiversity in these habitats in the coming decade.

Glossary

Chaparral Evergreen sclerophyllous-leaved shrublands that cover large areas of California.

Exaptation A trait that first evolved to serve one particular function, but subsequently comes to serve another.

Fynbos Evergreen sclerophyll vegetation dominating the Cape Region of South Africa.

Garrigue Low-growing secondzary evergreen shrublands that dominate extensive areas of the Mediterranean Basin.

Gondwanaland Former supercontinent of the Southern Hemisphere from which South America, Africa, Australia, and India are derived.

Kwongan Evergreen heathlands that cover extensive areas of southwestern Australia.

Maquis Vegetation cover of the Mediterranean Basin dominated by evergreen sclerophyllous shrubs and trees.

Matorral Evergreen sclerophyllous-leaved shrublands that dominate large areas of central Chile.

Mediterranean-type ecosystem (MTE) Habitat characterized by mild wet winters and warm dry summers. MTEs occur in California, central Chile, the Mediterranean Basin, the Cape Region of South Africa, and southwestern and South Australia, all at N and S latitudes of 30–35°.

Sclerophyllous Descriptive of leaves with a leathery texture due to the presence of sclerenchyma with large amounts of lignin and cellulose in their tissues.

Introduction

Mediterranean-type ecosystems (MTEs), with their characteristic and unique climatic regimes of mild wet winters and warm and dry summers, occur in just five regions of the world. These regions are California, central Chile, the Mediterranean Basin, the Cape Region of South Africa, and southwestern and South Australia (Figure 1, Table 1). Under this climatic regime, 90% or more of the annual precipitation typically falls in the 6 months centered on winter. The traditional boundaries of each region have been based not only on climatic regimes, but also on additional factors of floristics, vegetation structure, and historical precedent. Thus, there is not a single defining set of criteria for mapping the MTEs. Because of differing definitions of the boundaries of MTEs and the related biodiversity hotspots, data on species diversity for vertebrate groups differ between references.

Although frosts may occur throughout much of the MTE regions, these are infrequent and relatively mild in lowland areas. Mean annual precipitation is as low as 120–250 mm in coastal areas of the MTEs and reaches to about 900 mm at the upper margins of the classic evergreen shrub zone. Higher montane areas with winter rainfall regimes where the majority of precipitation falls as winter snow are also present within the traditional boundaries of MTEs. Although typically excluded from the boundaries of MTEs, adjacent arid regions that exhibit winter rainfall regimes (e.g., the Mojave Desert in California, Atacama Desert in Chile, Succulent Karoo in South Africa, and northern Sahara Desert) have a Mediterranean-type climate with a regime of winter rainfall.

Biodiversity is particularly notable in the MTE regions for vascular plant species. Although the combined area of these five regions is little more than 2% of the land area of the Earth,

MTEs are home to ~50,000 species of vascular plants (Table 2), 20% of the world's total of about 250,000 named species. Nowhere outside of lowland tropical rainforests are there ecosystems with higher regional diversities of species, providing a strong justification for each of these regions being designated as a global “hotspot” of evolution. Vertebrate diversity is variable, and less significant overall on a global basis, but highly diverse for many specific groups of reptiles and amphibians. Invertebrate diversity and endemism is high in some MTEs, notably bees and monkey beetles (Hopliini) in the Cape Region, and bees in the Mediterranean Basin.

A characteristic ecological feature of MTEs is the widespread dominance of evergreen shrublands dominated by species with sclerophyllous leaves (di Castri *et al.*, 1981; Cowling *et al.*, 1996; Dallman, 1998). The dense cover and biomass of these shrublands burn readily under dry summer conditions with low humidity, although with differing frequencies characterizing individual MTE regions as described below. Thus, there are morphological, ecophysiological, and phenological traits favoring postfire regeneration of these stands through resprouting and fire-stimulated reseeding. Also widely present in MTE sclerophyll shrub are adaptations (or exaptations) to tolerate low soil nutrient availability and restricted summer water availability.

Despite the general characterization of MTE regions as having dominance by evergreen shrublands, other vegetation forms are also present. Woodlands are widespread in most MTEs, particularly in areas with deeper or richer soils, or as riparian woodlands or gallery forests in wetter sites. Oak woodlands dominated by species of *Quercus* are widespread in California and the Mediterranean Basin, with both evergreen and deciduous species as dominants. These communities can take the form of closed canopy evergreen woodlands, grading

Figure 1 Global distribution of the five Mediterranean-climate regions. The position of 30 and 40° N and S latitudes are indicated by lines.

Table 1 Comparative area, topographic heterogeneity, climatic heterogeneity, and estimated natural fire frequency for the five Mediterranean-type climate regions of the world

Region	Area (10^6 km^2)	Topographic heterogeneity	Climatic heterogeneity	Natural fire frequency (years)
California	0.32	High	Very high	40–60
Central Chile	0.14	Very high	Very high	Almost fire-free
Mediterranean Basin	2.30	High	High	25–50
Cape Region	0.09	Moderate	High	10–20
SW Australia	0.36	Low	Moderate	10–15

Note: Vertebrate data from the Conservation International “hotspot” descriptions of the five MTEs (Mittermeier *et al.*, 2005).

into shrublands as in live oak woodlands of Southern California and the maquis of Europe, or open savannas of deciduous oaks that are widespread in both regions. Central Chile once had widespread dry- and wet-sclerophyll woodlands, but the dominance of these has been dramatically reduced by human activities. Evergreen woodlands dominated by *Eucalyptus* are widespread in Western Australia. Only the Cape Region of South Africa of all of the MTEs is largely lacking in woodlands, with such communities restricted to scattered stands of Afro-montane forest and subtropical thicket along the southern coast in fire-protected areas lacking in strong seasonal drought.

The evergreen, sclerophyll shrublands of California and Chile commonly grade off along drier coastal margins and at their arid interior margin to a plant community dominated by drought deciduous shrubs. This community, which may also dominate early successional disturbance sites or arid microsites in evergreen shrublands, is termed sage scrub in California and coastal matorral in Chile. Structurally similar communities with mixed dominance of low evergreen (and more rarely deciduous shrubs) are called phrygana in Greece and batha in the eastern Mediterranean Basin. Deciduous shrubs are largely lacking, however, from similar habitats in the Cape Region of South Africa and southwestern Australia.

Natural Disturbance Regimes

Although the five Mediterranean-climate regions share many aspects of natural climatic and environmental disturbance regimes, there are significant differences as well (Groves and di Castri, 1991; Rundel *et al.*, 1998; Rundel, 1999). While all five regions experience characteristic summer drought, for example, the magnitude of this drought is particularly severe in California and Chile, where 6–8 months or more may pass without measurable rainfall. Extreme drought such as this is rare in South Africa and southwestern Australia where summer months frequently have light showers and relatively high humidity.

The dense canopies of evergreen sclerophyllous shrubs make fire an important component of natural disturbance regimes. Natural fires, however, are significant ecological events in consuming aboveground vegetation in four of the five MTEs. Chile, where natural fires are a rare event, is the exception among MTEs. The Mediterranean-climate region of central Chile is protected from summer convective storms and lightning moving westward across Argentina by the high Andean Cordillera. The native flora of Chile shows little evidence that fire has been an important ecological disturbance regime in the evolution of life history characteristics.

Natural fire frequencies are quite different among the other four Mediterranean-climate regions (Table 1). In South Africa, for example, fynbos vegetation in the Cape Region commonly burns at intervals of 10–15 years, while in California natural frequencies are thought to be 30–50 years or more.

There are other strong environmental differences in addition to potential drought stress, which make the Cape Region of South Africa and southwestern Australia distinct from the other three MTEs. These two areas lie in geologically ancient and stable landscapes, resulting in highly leached and nutrient-poor soils. In contrast, earthquakes, volcanic activity, orogenic uplift, and other dynamic processes create natural disturbance regimes in California, Chile, and the Mediterranean Basin. Unlike South Africa and southwestern Australia, the younger landscapes of these three regions have experienced tremendous changes in climate regime and landscape structure in Quaternary and Holocene times and these changes have had profound impacts on community structure and speciation. The remarkable patterns of speciation in fire-sensitive shrub lineages in the Cape Region of South Africa and southwestern Australia likely have resulted from a combination of relatively mild and stable Cenozoic climatic conditions coupled with high fire frequencies in these nutrient-poor habitats.

Patterns of Speciation

Although there has been widespread speculation for many years on the causal factors responsible for the high levels of vascular plant biodiversity in MTEs, few clear generalizations have emerged. What is known is that there are conditions promoting the coexistence of seemingly ecologically equivalent shrubs, geophytes, and graminoids (Restionaceae) in frequently burned shrublands on nutrient-poor soils of fynbos and kwongan communities. Slow growth rates and diverse strategies of post-fire regeneration and reestablishment appear to promote this

coexistence (di Castri and Mooney, 1973; Kruger *et al.*, 1983; Davis and Richardson, 1995; Cowling *et al.*, 1996). MTEs on less-infertile soils and with longer intervals between fires (chaparral, matorral, maquis) have lower diversity as short-lived species are excluded by rapidly growing shrub dominants. Open woodlands in the Mediterranean Basin and California, however, may have very high local diversity of annuals and short-lived perennials, where grazing maintains open habitat for species establishment.

Regional topographic and climatic heterogeneity *per se*, which might be thought to be logical correlates of comparative diversity among the five MTEs, is a poor predictor of diversity (Table 1). Instead, natural selection has operated to allow for a fine-scale discrimination of habitats and niches under the selective pressures of stable climates, predictably frequent fires, and periodic drought that promote community turnover and diversification. Thus, fynbos in the southwestern Cape Region and kwongan communities in southwestern Australia have evolved species-rich landscapes in topographically homogeneous areas through successive events of rapid speciation of lineages coupled with low extinction rates. High predictability of interannual rainfall and relatively limited summer drought periods may be an important factor in this low level of extinction (Cowling *et al.*, 2005).

The different speciation histories of the MTEs are reflected in the phylogenetic structure of their floras. In the Cape and southwestern Australia, where environments have been relatively stable throughout large portions of the Tertiary, radiations of endemic lineages have occurred throughout the Neogene; in the other MTEs, most radiations are associated with the onset of Mediterranean climates in the late Miocene and dramatic climate changes beginning in the late Pliocene (Hopper *et al.*, 2009; Linder, 2005; Sauquet *et al.*, 2009).

Biodiversity in California

Introduction

The political boundaries of the state of California cover an area of $411 \times 10^3 \text{ km}^2$, but the area includes more than the core area of Mediterranean-type climate (Rundel and Gustafson, 2005). These political boundaries include winter rainfall portions of the Sonoran Desert and Mojave Desert, as well as areas of cold desert habitats east of the Sierra Nevada. The California floristic province, generally defined as the core MTE area, excludes these desert regions and adds northwestern Baja California and southern Oregon to the floristic province. Under this definition, the California floristic province covers $324 \times 10^3 \text{ km}^2$. Because of the differences between the political and floristic province boundaries of California, some caution must be used in assessing figures on California biodiversity in the literature.

The geomorphic structure of California is complex and the topographic diversity within the floristic region is very high. Thus, this region covers the Coast Ranges extending north and south along the state, the broad Central Valley, the Sierra Nevada range, and the Transverse Ranges of Southern California. The Coast Ranges reach elevations as high as 2700 m,

while Mt. Whitney in the Sierra Nevada is the highest point in the continental United States at 4400 m elevation. The Transverse Ranges in Southern California have a number of peaks reaching above 3000 m. The dynamic geologic history of uplift, faulting, and tectonics has produced complex mosaics of soil structure and parent material, and produced sharp climate shifts over the Quaternary with associated glaciation in the Sierra Nevada.

The foothill regions throughout most of California are typically dominated by mosaics of chaparral shrublands and both evergreen and deciduous woodlands with oak species as the typical dominants. These areas commonly receive 400–800 mm annual rainfall. Rainfall is strongly centered on the winter months, and 6 months without rain is common. Drier areas along the coast and inland at the transition to desert environments support coastal sage scrub dominated by drought deciduous shrubs and a few species of deeply rooted evergreen sclerophylls. Mountain areas above 1500 m in Northern California and 1800 m in Southern California show a transition to montane conifer forests, subalpine forests, and alpine communities with increasing elevation. Higher rainfall areas along the central and northern coast of California support mixes of conifer and hardwood forests, extending into massive coast redwood forests along the northwestern coast. Mean annual rainfall reaches its highest levels above 2500 mm in this region.

Vascular Plant Diversity

California as a political unit contains nearly 5000 native vascular plants species, with about 3500 of these within the California Floristic Province. For the most recent state flora, the total includes 97 ferns and fern relatives, 59 gymnosperms (53 conifers), 833 monocots, and 3987 dicots. The largest family in this flora is the Asteraceae with 627 native species, followed by the Fabaceae with 297 species and the Poaceae with 251 species. The largest five genera make up more than 10% of this total and include *Carex* (131 species, Cyperaceae), *Eriogonum* (112 species, Polygonaceae), *Astragalus* (94 species, Fabaceae), *Phacelia* (93 species, Boraginaceae), and *Lupinus* (71 species, Fabaceae). All of these genera comprise largely of herbaceous perennial and annual species. Notable speciation has also occurred in two shrub lineages, *Arctostaphylos* (Ericaceae) and *Ceanothus* (Rhamnaceae) (Raven and Axelrod, 1978).

Endemism at the species level is relatively high at 61% within the California Floristic Province (Stebbins and Major, 1965). Fifty-two genera are strictly endemic to this province. If another 14 genera that extend only slightly outside of the region into Arizona or Baja California are included, then 8.1% of the genera are endemic. This high level of endemism is heavily influenced by the diversity of annual plants that comprise 27.4% of the vascular plants of the California floristic province. For annual species alone, endemism is 65.3%.

The highest species richness of MTEs in California appears to occur in lightly disturbed grasslands and oak woodlands, where 47–64 species have been reported in 0.1 ha sites. These levels of diversity at this 0.1 ha scale are also matched in

postfire stands of chaparral where annual plant diversity is very high. Mature chaparral, however, often exhibits low levels of species diversity.

Vertebrate Diversity

The terrestrial mammal fauna of California includes about 160 species, with rodents making up more than half of this total. Among these, however, are 30 species restricted to the desert regions of the state and thus not part of the strict Mediterranean-climate region. That leaves a total of about 130 terrestrial mammals native to the shrubland, grassland, woodland, and forest regions of California. An additional five species which once occurred in the state have been extirpated in historical times. These include the grizzly bear, wolf, bison, jaguar (only an occasional visitor in the past), and giant deer mouse. Turnover between habitats (beta diversity) accounts for most of the diversity of mammal faunas, with alpha and gamma diversity relatively low.

Resident, breeding, and migrant bird diversity in California is about 350 species. Shore and marine birds make up 39% of this total. Passerines form the largest group of birds with 41% of the total. There are 21 species of hawks, vultures, and eagles, 13 species of owls, and 12 species of woodpeckers and flickers. Two bird species are endemic to California. These are the yellow-billed magpie and endangered California condor. Focusing on passerine birds, the alpha diversity of bird species across landscape gradients peaked in closed woodland and forest habitats, while species turnover between habitats (beta diversity) is greatest in mid-elevation chaparral.

There are 54 species of amphibians and 69 species of reptiles within the political boundaries of California. The salamander fauna is especially notable with 36 species, 24 of which are endemic. The reptiles include two turtles and tortoises, 33 lizards, and 33 snake species. However, the desert areas of the state are the habitats for 38 reptiles and amphibian species, thereby reducing the diversity of the California floristic region.

The native inland fish fauna of California includes 73 native species.

Biodiversity in Chile

Introduction

The political boundaries of Chile provide relatively natural biogeographic boundaries because of the topography of desert, mountain, and ocean boundaries. To the north is the hyperarid Atacama Desert, which reaches its extreme of conditions in the Tacna-Arica region along the Peruvian border. Here, a virtual absence of rainfall separates the Peruvian floristic elements of the desert from the Chilean elements. To the east, the Mediterranean-climate region of central Chile is strongly delineated by the high Andean Cordillera. Many peaks in this range reach well above 6000 m and effectively shield Chile from weather fronts moving westward across Argentina. Although major uplift of the Andes began in the

mid-Tertiary, at least 14 Ma, the range continues to be tectonically active today. The elevation of mountain passes along the Andes in northern and central Chile are too high to allow easy migration of either plants or animals, and thus have helped to isolate the flora and fauna of Chile. Only in southern Chile where the Andes are lower has there been easy migration across this range. However, the severe climatic conditions of cold that characterize Patagonia in southern Chile act to strongly reduce the biological diversity in this area.

Comparisons of species diversity between Chilean organisms and those of other Mediterranean-climate regions deserve some caution in terms of the area included. As with California, the political boundaries of Chile include desert and wet forest ecosystems that are not comparable with core Mediterranean-climate habitats. Most figures for Chilean diversity in the literature are based on political boundaries. An additional issue of political boundaries comes in assessing levels of endemism for the Chilean flora or fauna. Levels of endemism for all groups are much lower if strict adherence to the political boundaries of Chile rather than the more natural boundaries of the Chilean/Patagonian biogeographic province is taken into account.

Much of central Chile, which covers an area of about $140 \times 10^3 \text{ km}^2$, shares a physiographic structure parallel to that of California. Moving inland from the Pacific Ocean, there is typically a coastal range of mountains, a broad central valley, and a high mountain range to the east. The geologically recent Cordillera de la Costa is relatively high west of Santiago at about 33° S latitude, with the major peaks Cerro Campana (1910 m), Campanita (1510 m), and El Roble (2220 m). These peaks are high enough to intercept moisture from humid southwestern winds, producing woodland areas with significant fog interception and thus improved water relations.

The dominant vegetation in central Chile is matorral, an evergreen shrubland similar in general form to chaparral (Rundel, 1981). Along the coast and to the north this community grades into a coastal matorral with a greater dominance by drought deciduous shrubs. At higher elevations and on sites with greater water availability, matorral grades into a sclerophyll woodland community, and to the south into hygrophilous woodlands with many species characteristic of the Valdivian forest region to the south. Much of the central valley of Chile today is dominated by a savanna community termed espinal, with *Acacia caven* as the sole dominant. This community is almost certainly the result of human intervention on landscape processes over the past four centuries. Sclerophyll woodland and matorral would once have covered much of this area.

Unlike California and the Mediterranean Basin, the high mountains of the Andean Cordillera in central Chile do not have a forest zone except in the southern margin of the central region. The young age of these mountains and lack of soil weathering has produced unstable geological conditions on the west-facing slope of the Andes. Matorral communities on the lower foothills of the Andes give way to a low and scrubby montane matorral community at about 2000 m elevation.

The biological diversity of Chile has an ancient origin that dates back to Gondwanaland. Southern Chile in particular exhibits many broad biogeographical linkages with New

Zealand and Australia. Central Chile shows other biogeographical connections with southeastern Brazil, a linkage dating back to mid-Tertiary times before the uplift of the Andes. Since the Andean uplift, however, the biota of Chile has evolved largely in isolation from other biogeographic regions.

Biosystematic and biogeographic knowledge of the flora and fauna of Chile has increased greatly in recent decades, and thus the biodiversity of most groups of vascular plants and vertebrates is relatively well known (Simonetti *et al.*, 1995). These syntheses have been applied more generally to the country as a whole, however, rather than to discrete regional areas. Thus, there is a strong need for more regional studies that evaluate patterns of alpha, beta, and gamma diversity in relation to environmental gradients.

Vascular Plant Diversity

The age and evolutionary isolation of the Chilean flora is clearly indicated by the large number of families that are largely endemic to the Chilean floristic region, which includes adjacent areas of austral forest in southern Argentina. Endemic families entirely restricted to Chile are the Aextoxicaceae, Gomortegaceae, and Lactoridaceae and Thyrsopteridaceae (restricted to the Juan Fernandez Islands). Other families that are largely Chilean in distribution but cross political boundaries into desert areas of Peru or austral forests of southern Argentina are the Malesherbiaceae, Mizodendraceae, and Francoaceae. Of these endemic families, the monotypic Aextoxicaceae and Gomortegaceae have distributions centered in the Mediterranean-climate regions of central Chile, while the Malesherbiaceae is centered in the coastal deserts and adjacent arid montane regions of northern Chile and southern Peru.

For continental Chile as a political unit, the vascular plant flora consists of ~4600 native species, divided into about 850 native genera and 180 families. This flora includes 124 species of ferns and fern relatives, 13 species of gymnosperms, and about 4500 species of Angiosperms (Marticorena and Quezada, 1985). The flora of central Chile, excluding the desert areas north of La Serena, the Juan Fernandez Islands, and the forest and moorland areas south of Concepción, is estimated to be about 2400 species. The current concept of the biodiversity "hotspot" of central Chile has been recently expanded well beyond the Mediterranean-climate regions to include the Atacama Desert, Juan Fernandez Islands, and the Valdivian forest region. Thus, under this greatly expanded definition, the flora includes 3539 species.

Endemism is high at the generic level in the Chilean flora. Extrapolating from the literature, 16% of Chilean genera are strict endemics restricted to the political boundaries of the country. Another 17% of the genera are endemic to austral regions of Chile and adjacent areas of Argentina. Together, then a third of the genera are endemic to the Chilean-Patagonian floristic province. There are 22% of the genera with broad South American patterns of distribution and 10% of the genera have Gondwanaland origins with extant species in New Zealand and/or Australia.

The levels of species-level endemism within groups of the Chilean flora are high, but the values reported vary somewhat

depending on whether or not the author is quoting distributions within the strict political boundaries of Chile. A more natural view of endemism would include Andean species or austral forest and moorland species that occur within communities of the Chilean-Patagonian biogeographic province that may extend into Argentina. Using the political boundaries of Chile, one authority estimated that 62% of the vascular plant species were endemic, while others estimate about 50–55%.

A rich flora high in endemism occurs on the oceanic Juan Fernandez Islands, which lie about 500 km off the central Chilean coast and contain floristic elements from both the mainland of Chile and Polynesia. The flora includes 361 species of vascular plants, of which 60% are endemic.

The 20 largest genera of Chilean vascular plants make up about 30% of the flora. This group is led by *Senecio* (Asteraceae) with 218 species, *Adesmia* (Fabaceae) with 140 species, *Oxalis* (Oxalidaceae) with 111 species, *Calceolaria* (Scrophulariaceae) with 86 species and *Calandrinia* sensu latu (Portulacaceae) with 70 species. As might be expected, the degree of endemism within the largest families is higher than that for the flora overall. Eleven of the 20 largest families have 80% or more of their species endemic to Chile. These numbers on species diversity and endemism will no doubt change to some extent as these large and difficult genera become better studied. One of the most charismatic of endemic species is the Chilean wine palm, *Jubaea chilensis*. This large palm was once widespread through central Chile but is much restricted in distribution today.

Vertebrate Diversity

Mammal diversity in Chile, as in other parts of temperate South America, is low. It has been suggested that severe climatic conditions associated with Pleistocene glacial movements in the Andes may have had a strong impact in reducing the diversity of temperate mammal faunas in South America. Major faunal extinctions were also present in South America at the end of the Pleistocene, as in North America, and these extinctions have been associated with the arrival of early man. Many ecological niches in temperate South America appear to be incompletely occupied by mammals in comparison with North America.

Chile has a mammal fauna of 99 native terrestrial species, with 64 species occurring within the hotspot region. Five genera are endemic. The largest single group is the Rodentia, and comprises 60% of this total. Next in abundance are the Carnivora with 14%, and the Chiroptera (bats) with 10%. Large mammal species are particularly low in number. These include species of felids (puma, Geoffrey's cat, and colo colo), three species of canids (all fox species of *Pseudolopex*), four camelids (guanaco, vicuna, and the domesticated llama and alpaca), and three cervids (huemul, northern huemul, and pudu). Mammal faunas of Chile have been placed into five biogeographic groupings: the summer rainfall Altiplano region of northeastern Chile, the Atacama Desert and adjacent winter rainfall Andes of northern Chile, the Andes of central Chile, the Mediterranean-climate region of central Chile, the austral forests of southern Chile, and the Patagonian region. The monito del monte

(*Dromiciops gliroides*) forms an endemic family, the Microbiotheriidae. In addition to these native mammal faunas, there are 15 species of terrestrial mammals that have become naturalized in Chile. Five of these occur only on the Juan Fernandez Islands, where they have had an extreme impact on the structure and composition of the native flora.

The total bird diversity of Chile is only moderate. Including the oceanic islands of Pascua and Juan Fernandez and the Antarctic territory claimed by Chile, there are reports of 451 native species and five introduced species for Chile. The hotspot area includes 226 species, with 12 of these being endemic. The biogeographical isolation of the Chilean bird fauna shows parallels with that of the mammal fauna in the manner in which niches have been filled in unusual manners. Corvids, for example, are absent from Chile. Their role as scavengers has been filled by caracaras.

There are 87 native species of terrestrial reptiles in Chile, divided among seven families and 18 genera. These include six snakes (four genera) and 81 lizards (14 genera). For the hotspot boundaries, there are 41 reptile species, with 27 of these being endemic. The diverse lizard fauna of Chile is strongly dominated by the family Tropiuridae, in particular the iguanid genus *Liolaemus*. This diverse genus and its evolution have been the focus of a large number of ecological and evolutionary studies. The occurrence of distinctive populations within individual species has led to the designation of a large number of subspecies. There are two endemic species of snakes.

The highest diversity of reptiles in Chile occurs in the northern desert and Andean areas, outside of the core Mediterranean-climate region. This region is also the site of the greatest degree of endemism.

The amphibian fauna of Chile exhibits an unusually high level of endemism, in comparison with other vertebrate groups. There are 43 native species in the hotspot of Chile, with five of the 12 genera endemic. The highest diversity of these amphibians is located in the forested regions of south-central Chile. Notable for their absence are salamanders, with only frogs and toad species present. More than three quarters of the native frogs and toads are endemic to Chile. Many of these endemic species are quite rare and localized in distribution.

The native fish fauna for the Chilean hotspot region includes 43 species, including two endemic families.

Biodiversity in the Mediterranean Basin

Introduction

The Mediterranean Basin represents the largest area of MTEs in the world, covering a complex landscape with a large amount of topographic and climatic heterogeneity. The total area of the region is $\sim 2.3 \times 10^6$ km², nearly 10 times greater in size than any other MTE region. This area includes more than 20 nations arrayed on both sides of the Mediterranean Sea. While coastal areas are extensive because of the large archipelagos and islands within the Mediterranean, much of this area consists of mountainous terrain with many areas above 2000 m elevation and peaks reaching as high as 4500 m.

The geographic position of the Mediterranean Basin is also an important factor in understanding the biodiversity of this region (Blondel *et al.*, 2010). Lying at the juncture of three continental landmasses, it holds a geologic history with dynamic changes associated with plate tectonics, mountain uplift, and active vulcanism. Strong climatic shifts that took place during the Plio-Pleistocene period, most notably major glacial episodes, resulted in a telescoping of many communities into the Mediterranean Basin and provided for opportunities for geographic isolation and speciation. In contrast to other MTEs, the great majority of the Mediterranean Basin is underlain by limestone. Local areas of volcanic or siliceous parent material are also present.

The climatic features of the Mediterranean Basin are often used to define this region, but the range of dominant and widespread woody species such as holm oak (*Quercus ilex*) and olive (*Olea europea*) are also used as bioindicators of the region. To the north, the Mediterranean-climate region grades into more mesic regions with summer or year-round patterns of rainfall. To the south, the Mediterranean region intergrades with the winter rainfall desert of the northern Sahara. Climates of the Mediterranean Basin are notable for their high interannual variation in both rainfall and temperature extremes.

The large area of the Mediterranean Basin, coupled with its topographic and climatic heterogeneity, makes for complex assemblages of vegetation types. There are extensive woodlands dominated by both evergreen and deciduous species of oak and evergreen sclerophyllous shrublands of many forms. These shrublands are often differentiated into types depending on the height of the vegetation. Tall sclerophyllous shrublands that may include small evergreen trees are termed maquis. Several species of Mediterranean pine may be present in this community. A middle height shrubland, generally occurring on calcareous substrates, is termed garrigue. Finally, low semiarid evergreen shrublands in the eastern Mediterranean Basin are commonly termed phrygana in Greece and batha in Israel. A long history of human impacts on the natural landscape has strongly impacted community structure and diversity.

Vascular Plant Diversity

The vascular plant flora of the Mediterranean Basin is estimated to include about 25,000 species (22,500 native species), making this region the richest among MTEs in total plant diversity. By comparison, the remaining portions of Europe with non-Mediterranean-type climate regimes cover four times as much area but have only about 6000 vascular plant species. This large flora in the Mediterranean Basin is a broad mixture of species with disparate evolutionary histories and biogeographic origins (Medail and Quezel, 1997).

One group of species evolved under subtropical conditions that existed in this region prior to the Quaternary. These include such woody plant genera as *Arbutus* and *Calluna* (Ericaceae), *Ceratonia* (Fabaceae), *Chamaerops* (Arecaceae), and *Laurus* (Lauraceae). Another group of taxa represents neo-Mediterranean elements that migrated into the Mediterranean Basin after the establishment of a Mediterranean-type climate.

Examples of woody genera in this group include *Amelanchier* (Rosaceae), *Clematis* (Ranunculaceae), and *Cistus*, *Halimium*, and *Helianthemum* (Cistaceae). Three groups of nontropical woody elements that evolved after the onset of Mediterranean-type climates have been identified. These groups are a Mediterranean element evolved *in situ* in mountain areas and high in endemism, a desert and cold steppe group of species entering from Africa and the Middle East, and a Holarctic element of species with Eurasian temperate affinities. Endemism is high at the species level in the Mediterranean Basin, with a level of about 50%.

Species richness at the scale of 0.1 ha is often remarkably high in lightly grazed or disturbed Mediterranean woodlands and shrub grasslands, with as many as 119–179 species in such stands.

Vertebrate Diversity

Vertebrate faunas of the Mediterranean Basin share the characteristic of multiple biogeographic origins with vascular plants. Dramatic climatic oscillations during the Pleistocene led to periodic turnovers of Eurasian and African faunal elements and a resulting isolation of populations.

The present fauna of land mammal species for the Mediterranean Basin number about 224 species of which 25 are endemic. Because of the biogeographic barriers of the Mediterranean Sea and the Saharan Desert, mammal faunas of Mediterranean Europe, the Middle East and North Africa are somewhat distinct. For North Africa, the mammal fauna of the Mediterranean Basin shows its strongest affinities with tropical Africa. A decline in species richness occurred at the end of the Pleistocene and into the Holocene with a combination of sharp climate shifts and human pressures through hunting.

Bird diversity of the Mediterranean Basin includes about 497 regularly occurring species. In contrast to mammals, the affinities of bird faunas are more strongly linked to the Asiatic steppes than to tropical Africa. The evolution of these elements of bird faunas can be linked to Eurasian (153 species) and Eremian semiarid habitats (85 species), where Plio-Pleistocene conditions led to ongoing isolation and speciation. Forest birds of boreal origin are widespread and dominant throughout both Middle Europe and the Mediterranean Basin. Shrubland bird species characteristic of the region represent only about 12% of the total. There are 32 endemic bird species in the Mediterranean Basin.

Reptiles and amphibians of the Mediterranean Basin include 228 and 77 species, respectively, and show distinct Holarctic affinities. Much of the endemism within these groups appears to represent archaic lineages that differentiated during the Middle Tertiary. Reptile diversity is highest in the eastern Mediterranean Basin and drops steadily moving westward. Species diversity on Mediterranean islands is relatively low. Important reptile groups include lizards of the Lacertidae with 63 species (23% of the world total), snakes of the Viviperidae with 19 species (8% of the world total), and tortoises of the Testudinidae with four species. Overall, 34% of Mediterranean Basin reptiles are endemic to this region. For amphibian diversity, the pattern is reversed compared with

reptiles as the highest levels of diversity are found in the Euro-Mediterranean areas compared with the North African and Middle Eastern portions of the region. Notable groups of amphibians include the Discoglossidae with 10 species (71% of the world total) and the Salamandridae with 19 species (36% of the world total). Endemism for amphibians in the Mediterranean Basin is 31%.

Fish diversity is relatively high in the Mediterranean Basin compared to the other MTEs, with 216 species. This group includes 63 endemic species, six endemic genera, and one endemic family.

Biodiversity in the Cape Region of South Africa

Introduction

The Cape Region forms a small area on the southwestern tip of the African continent. It is renowned for its showy and diverse flora unlike that of any other area of the world. The landscape of the Cape Region is dominated by steep and strongly folded mountain ranges of quartzitic sandstone that predate the separation of the African continent from Gondwanaland. These once high mountains have been eroded over the past 200 My to form low ranges capped by resistant Table Mountain sandstone. Separating the mountains are gentle valleys and undulating plains that are largely underlain by shales with greater nutrient availability. Relatively young Tertiary and Quaternary limestones and sands mantle extensive areas of the coast.

The characteristic vegetation of the Cape Region, particularly on the nutrient-poor quartzite soils, is fynbos (Cowling, 1992; Cowling and Richardson, 1995). Fynbos is an evergreen shrubland dominated by four major plant morphological groups. These include two shrub groups (the proteoids and ericoids), a sedge-like group (restioids), and geophytes. The proteoids, formed by woody Proteaceae, form the tallest matrix of the fynbos community and commonly reach to 2–4 m in height. The ericoid group gains its name from the Ericaceae, but includes more than 3000 species of small-leaved shrubs representing many families. The restioids are members of the Restionaceae, a family with origins in Gondwanaland but its primary diversification in the fynbos. Finally, the Cape Region contains the highest diversity of bulbs and other geophytes in the world, with more than 1500 species. Many types of fynbos have been described, but a simple classification scheme includes proteoid fynbos, ericaceous fynbos, restioid fynbos, asteraceous fynbos, and grassy fynbos (Manning, 2007).

Another important shrubland vegetation type of the Cape Region is renosterveld, a low shrubland occurring on richer soils with shale parent material. It is floristically differentiated from fynbos by the absence of restioids and minor importance of proteoids. This community once covered more than a quarter of the Cape Region, but has now largely been cleared for agriculture and urban expansion.

Woodland and forest communities are surprisingly rare in the Cape Region. True forests occupy only about 3850 km² of moist sites (800–1200 mm annual rainfall) protected from fire along the southern coast. These forests are low in diversity

and represent depauperate outliers of Afro-montane forests of tropical East Africa Subtropical thicket, a low, evergreen formation with floristic affinities to Afro-montane forest, occurs throughout the Cape Region in fire-free sites. This community is richer in species and endemics – especially succulents – than the moister Afro-montane forests (Vlok *et al.*, 2003). It appears that fire and not climate is the major determinant of the occurrence of these communities. The quasi-Mediterranean south coastal region has markedly fewer occurrences of high fire danger days.

Vascular Plant Diversity

The Cape Region contains what is arguably the most distinctive and diverse floras of any temperate area of the world (Goldblatt and Manning, 2002). Its status as a distinct floral kingdom is reinforced by the presence of five endemic families – Geissolomataceae, Grubbiaceae, Penaeaceae, Roridulaceae, and Stilbaceae. Moreover, there are 193 endemic genera, which is 19.5% of the total.

Covering an area of only 78,500 km², the Cape Region contains ~9000 species of vascular plants. The 10 largest genera of the Cape Region account for over 20% of the flora, led by *Erica* (Ericaceae, 658 species) and *Aspalathus* (Fabaceae, 257 species). Other large genera are *Phyllica* (Rhamnaceae), *Agathosma* (Rutaceae), *Oxalis* (Oxalidaceae), *Pelargonium* (Geraniaceae), *Senecio* (Asteraceae), *Cliffortia* (Rosaceae), *Muraltia* (Polygonaceae), and *Ruschia* (Aizoaceae-Mesembryanthema) (Goldblatt and Manning, 2000).

Levels of species endemism in the Cape floristic region are among the highest in the world. For the entire region, endemism at the species level is about 69%. The high levels of endemism present in the Cape Region are largely due to the presence of neoendemics rather than paleoendemic species, although many neoendemic lineages begin diversifying in the mid Cenozoic. This dominance of neoendemics is indicated by the predominance of endemic diversity in large, species-rich genera, the widespread presence of sympatric congeners, and the edaphic specialization of many endemics on geologically young substrates. Rather than being a random ecological or phylogenetic assemblage of species, the great majority of endemics are low shrubs killed by fire and dependent on closely dispersed seeds for regeneration. Four families are notably rich in endemics – the Proteaceae, Ericaceae, Rutaceae, and Polygalaceae. Species richness is greatest in the southwestern Cape Region centered around Cape Town. The Cape Peninsula, for example, supports 2256 species (including 90 endemics) in an area of 471 km². Cape Hangklip on the eastern shore of False Bay near Cape Town has 1383 species in 240 km².

Smaller regional centers of endemism exist within the Cape Region. Dividing the Cape Region into five floristic zones on the basis of species distributions within seven large families, regional levels of endemism are highest in the southwestern and northwestern Cape (about 50%) and lowest in the Eastern Cape and Inland Mountain regions with nonseasonal rainfall (18–28%). These patterns of regional endemism have been further demonstrated in studies of distribution of the Proteaceae in the Cape Region. For the entire Cape Region, 99.4% of

the 330 species of Proteaceae are endemic. At a regional level, 63% of the Proteaceae in the southwestern region are endemic to that region, compared with only 19% endemism for the Coastal Mountain and southeastern regions. Point endemism is also widespread involving species that are restricted to highly specific edaphic habitats.

Fynbos species diversity is also extremely high at the alpha-diversity level of small stands. Typical fynbos communities support a mean of about 65 vascular plant species in 0.1 ha, with a range of 31–126 species. Renosterveld shrublands have even higher diversities with a mean of 84 species per 0.1 ha and a range of 28–143 species.

Vertebrate Diversity

The Cape Region lacks a distinctive mammal fauna. This region today contains 127 species of native mammals, with 90 being present in the Southwest Cape area. The regional total is less than half of the mammal species occurring within all of South Africa. The largest orders present are the Rodentia and the Carnivora. The rodents are represented by two species of mole rats (Bathergidae), a porcupine (Hystricidae), two dormice (Muscardinidae), and at least 21 species of Muridae and Cricetidae. There are 27 species of the Carnivora, ranging from mustelids and civets to larger hyenas, jackals, and cats. Large browsers and grazers play an important role in this ecosystem in comparison with other MTEs. There are 20 species of Artiodactyla and five species of Perissodactyla. Very few of these depend on grazing, however, because of the paucity and poor nutritive value of Cape Region grasses. The Chiroptera is a large group with one fruit bat and 14 species of Microchiroptera in the Southwest Cape.

The abundance and diversity of native mammals was probably always relatively low in fynbos shrublands, unlike the rich savanna regions of the continent. At the time of European colonization the highest numbers and diversity of large mammals was present in renosterveld or other open communities with better browse. Large mammals that were once common on the renosterveld plains included bontebok, eland, buffalo, Cape mountain zebra, red hartebeest, and lion.

Endemism, as might be expected, is quite low among mammals in the Cape Floristic Region as most of this fauna extends northward or westward into arid or savanna ecosystems. Only four species in the mammal fauna are endemic. The fossorial Cape dune mole rat and burrowing gerbil among the endemic rodents are associated with sandy soil substrates rather than with any specific vegetation type. The colonial behavior and feeding specialization of mole rats on bulbs may be linked to the remarkably high diversity of geophytes in the Cape Floristic Region.

The regularly occurring bird fauna includes 324 species, with a notable diversity of Falconiiformes with 22 species. Six bird species are endemic. Endemic species are largely dietary specialists such as the Cape sugarbird, orange-breasted sunbird, and protea seedeater that are tied to specific plant resources in the fynbos. The originally direct communication of fynbos habitats with semiarid and savanna shrublands has probably been a factor in limiting the number of endemic fynbos birds. The savanna region of South Africa is far richer

in endemic species. At least four of the endemic fynbos birds are characteristic of montane areas or are allied to montane species of East Africa that live in ericaceous shrublands. For fynbos communities specifically, there are only about 10 reported species, with renosterveld habitats generally richer at a local level.

The Cape Region is moderately diverse in reptiles with 100 species present, 22 of which are endemic. Fynbos communities may contain more than 50 species of lizards. The Gekkonidae are the most important group with 18 species. There are 32 species of snakes reported from the Western Cape area. Among snakes, the Colubridae have the highest diversity with 25 species. There are 19 endemic species among the reptiles, 17% of the total. One notable endemic to the southwestern Cape Region is *Psammobates geometricus*, one of the rarest tortoises in the world. The life history of this species seems to have evolved to adapt to fynbos fire cycles, with hatchlings appearing in late autumn after the danger of summer fires is past.

Amphibians are relatively low in diversity in the Cape Region with 51 native species, 16 of these endemic. The largest single group of amphibians is the Ranidae with 13 species. One of the most interesting endemics among amphibians is the arum lily frog, *Hyperolius horstocki*, which lives in the flowers of the common arum lily (*Zantedeschia aethiopica*).

There are 34 native fish species in the Cape Region, 14 of these being endemic.

Biodiversity in Southwestern Australia

Introduction

Core Mediterranean-climate conditions are present in southwestern Western Australia and in South Australia around Adelaide (Hobbs, 1992). The core Southwestern Floristic Province of Western Australia is $\sim 357 \times 10^3 \text{ km}^2$ in area, similar in size to the California floristic province. A broader region with transitional rainfall patterns with biseasonal distribution is often included as well, almost doubling the core MTE area. While mean annual rainfall is commonly 350–800 mm over much of southwestern Australia, it reaches as high as 1500 mm at the extreme southwestern corner of Western Australia and drops to a low of about 250 mm at the eastern edge of the Mediterranean-climate region in a transition to arid communities. Topographic heterogeneity is very low over this region, with elevations of the few mountains reaching to no more than 1000 m. Much of the region is a low, laterized plateau dissected into broad valleys with deep *in situ* weathering. Soils of southwestern Australia, as in the Cape Region of South Africa, are generally very old, highly weathered, acidic, and low in nutrient availability.

For the true Mediterranean-climate regions, the highest rainfall zones with 800–1200 mm of annual rainfall support evergreen forests and woodlands dominated by *Eucalyptus marginata* (jarrah), *E. calophylla* (marri), *E. diversicolor* (karri), and *E. gomphocephala* (tuart). Low *Banksia* woodlands and coastal heaths are also widespread. At intermediate rainfall regimes of 300–800 mm, the dominant vegetation is a mosaic of shrubby woodlands (mallees) and heathland communities termed

kwongan (Pate and Beard, 1984). The vegetation and dominant species are finely tuned to small changes in edaphic conditions that influence nutrient and water availability. Human impacts on these ecosystems have been severe over the past century.

High levels of species diversity and endemism characterize the vascular plant flora, with only moderate diversity and endemism present in most vertebrate groups (Hopper and Gioia, 2004). The high levels of vascular plant diversity has been related to the development of a complex mosaic of landforms and soils during the Tertiary and Quaternary, the geologic history of oscillating moisture regimes through the Quaternary in the absence of glaciation, isolation of southwestern Australia from the east by the arid Nullarbor Plain, and interactions of gene pools from both paleotropical and temperate assemblages.

Vascular Plant Diversity

The Australian MTE regions including southwestern Australia and South Australia include at least 9000 species of vascular plants. There are about 7400 species present within the Southwest Botanical Province of Western Australia (Hopper and Gioia, 2004). Including species that extend slightly beyond the Southwestern Botanical Province into a transitional interzone, 79% of the flora is endemic. Included are 87 endemic genera and four endemic families – the Ecdeiocoleaceae, Cephalotaceae, Emblingiaceae, and Eremosynaceae. Woody perennials in four families – the Myrtaceae, Proteaceae, Fabaceae, and Ericaceae (Epacridaceae) – dominate the flora (Marchant *et al.*, 1987; Beard *et al.*, 2000). Much of the high species diversity within these families is due to extensive radiation within a few large genera. Large genera for the region include *Acacia* (400 species), *Eucalyptus* (246 species), *Grevillea* (200+ species), *Stylidium* and *Melaleuca* (150+ species each), and *Hakea* and *Caldenia* (100+ species each).

Nodes of unusual species diversity are present along the south coast of Western Australia (Stirling Range, Fitzgerald River area) and in the sandplains north of Perth (Mt. Lesueur area). As in the fynbos of South Africa, large numbers of endemics with highly local patterns of distribution also characterize kwongan. Local scale plant diversity reaches almost as high as areas in the western Cape Region of South Africa. Vascular plant diversity in a sample of 0.1 ha stands of heathland in southwest Australia exhibited a range of 43–103 species, while jarrah forests and mallee stands had a lower range of 17–55 species.

At the regional level, southwestern Australia exhibits major differences in centers of highest diversity among the most important woody genera. Some genera – as, for example, *Banksia* (Proteaceae), *Adenanthos* (Proteaceae), *Leucopogon* (Epacridaceae), and *Eucalyptus* (Myrtaceae) – are most speciose near the south coast or in southern kwongan and mallee communities. Other large genera have their highest diversity in northern kwongan – *Grevillea* (Proteaceae), *Conostylis* (Haemodoraceae), and *Lechenaultia* (Goodeniaceae). Finally, a large group of genera show bimodal patterns of diversity reflecting both the nodes of high species diversity in northern and southern kwongan – *Calothamnus* (Myrtaceae), *Melaleuca* (Myrtaceae), *Hakea* (Proteaceae), *Darwinia* (Myrtaceae), and

Dryandra (Proteaceae). Two other large genera, *Acacia* (Fabaceae) and *Verticordia* (Myrtaceae), are most diverse in the inland transition area of rainfall.

Vertebrate Diversity

The vertebrate fauna of Australian MTEs shows no unusual level of high diversity or endemism. The majority of the fauna in these MTEs are populations of more typically arid or mesic habitat species whose ranges extend into southwestern or South Australia. Thus, the majority of the vertebrates appear to have relatively broad ecological niches rather than specialized requirements unique to the MTEs.

For mammals, the Mediterranean-climate fauna includes only 57 species, 12 of these being endemic. Interpreting the patterns of distribution of large mammals is made difficult, however, by the strong impact that both Aboriginal and European populations have had on this fauna. The extinction of a large megafauna in the Late Quaternary left the Australian continent without large grazers or predators.

Bird diversity is also relatively low, with 285 species regularly present. Ten of these are endemic. Most notable among these endemics is the black swan (*Cygnus atratus*), shown on the state emblem for Western Australia.

Diversity is high among reptiles in southwestern Australia, an evolutionary consequence in part of the low mammal diversity. There are 177 native species, with 27 of these being endemic. Amphibians include 33 native species, with 19 endemic species and four endemic genera.

With only small areas of riverine or freshwater habitat, fish diversity in southwestern Australia is low. Only 20 native species are present but half of these are endemic. These include three endemic genera and one endemic family.

Conclusions

Mediterranean-type ecosystems provide many opportunities for comparative studies of the controlling factors in the evolution of biodiversity. These five regions share common characteristics of climatic regime, with an independent evolution of plant and animal species adapted to these conditions within each region. Thus, they provide a natural ecosystem experiment with five independent replications. The value of comparative studies then between these regions lies not only with their similarities, but with subtle differences in climatic conditions, topographic diversity, evolutionary history, and human impacts that have led to the patterns of diversity that we see today.

There has been a long history of comparative ecosystem studies between California and Chile (Cody and Mooney, 1978), and between South Africa and southwestern Australia, and these have traditionally devoted some attention to comparing and contrasting how natural processes operate. The remarkable biodiversity of MTEs together with the large numbers of rare and endangered species in these regions gives a special significance to expanding studies of these regions to better understand the evolution of diversity, particularly by vascular plants. Serious threats of habitat transformation and

degradation today make it critical that there be a better understanding of the conservation biology and sustainable resource management in all five MTEs (Rundel *et al.*, 1998; Rundel, 1999).

Glossary

Allopatric Describing two taxonomic entities whose geographic ranges do not intersect with each other.

Endemism The fact of being found in a specific location of limited size, rather than being widely distributed.

Eremic Relating to or occurring in desert regions.

Parapatric Describing two taxonomic entities whose geographic ranges are distinct but adjacent to each other.

Xeromorphic Describing a form that has developed in response to highly arid conditions.

The Levant

The Levant is the eastern shoreland of the Mediterranean (Por, 1975), a stretch of land approximately 800 km long and approximately 150 km wide (Figure 1). It is wedged in between the Mediterranean Sea in the west and the Arabo-Syrian Desert in the east, stretching from the mouth of the River Orontes in the north to the Isthmus of Suez in the south. It consists of four basic north–south-oriented features: the coastal plain, the western (cis-rift) mountains, the rift valley, and the eastern (trans-rift) mountains. In the east it merges gradually into the Arabo-Syrian Desert.

The 800-km-long Levant has several climatic and floral belts. In its northern (and high-altitude) areas the overall habitat is Mediterranean: Summers are dry and warm, and winters are rainy and mild with occasional snow in the higher mountains. Natural plant associations consist of xerophytic shrubs and trees. In its southern and eastern areas (the Negev, Sinai, and fringes of the Syrian desert) the overall habitat is eremic: Temperatures are high, precipitation is low and very irregular, and the vegetation cover is poor. Between these two major habitats there is an intermediate habitat of steppe character. The combination of the four major north–south relief patterns with the three climatic belts imparts an unusual heterogeneity to this relatively small zoogeographic province and has resulted in a highly dynamic faunal history.

The Extent of Biodiversity

It is difficult to estimate animal diversity throughout the whole Levant because there is better knowledge about the fauna of its southern than of its northern areas. Unfortunately, the term “southern Levant” is loosely applied by various authors to include the area of Israel, and sometimes also the Palestinian Autonomy, and/or Sinai, Jordan, and the Golan Heights. These limitations should be taken in account when considering the data (of representative groups) in Table 1. They suggest that animal diversity in the Levant is high and perhaps that this area is one of the richest and most diverse natural regions among temperate regions of the world (relative to its size). For example, the area between the Mediterranean Sea and the Jordan River, together with the Golan

Heights, is only approximately 28,000 km², but it contains approximately 170 bird and 100 mammal species (breeding). These numbers are not markedly fewer than those in California (210 birds and 110 mammals in an area of

Figure 1 The Levant; its eastern boundary (stippled line) is hazily defined (adapted from Por FD (1975) An outline of the zoogeography of the Levant. *Zool. Scripta* 4: 5). Reprinted with permission from Wiley.

Mammals (Mammalia), breeding	100	Southern Levant	Yom Tov (1988)

404,000 km²), whose southern part lies at the same latitude as Israel.

Several factors contribute to this high diversity. One is the lack of a major disastrous disturbance; the general pattern of the landscape in the Levant has persisted since the early Pliocene. Only minor areas of the Levant (the tops of Mt. Lebanon and Mt. Hermon) were ever glaciated to any considerable extent, and only small regions (e.g., the Golan) were subject to volcanic eruptions that covered large areas with basalt. Consequently, the Levant never suffered the catastrophic wipeouts that hit northern and central Eurasia many times throughout the Pleistocene.

Local, region-scale changes did occur, however, repeatedly separating and then uniting different patches of landscape, thus permitting possible speciation under allopatry. These local geological events probably contributed, through speciation and through invasion, to enrich rather than to impoverish the Levantine fauna. This long, generally eventless but locally eventful history of the Levant is one of the reasons for its rich fauna.

A further reason is the heterogeneous climate. Mean annual rainfall may decrease from 1000 mm to less than 100 mm over a short distance of 150 km. The landscape therefore changes from Mediterranean oak maquis to batha and then to barren deserts, and the fauna gradually changes as one species replaces another. The net result is a fauna richer than would be expected were the landscape more uniform.

In contrast to factors contributing to biodiversity of the Levant, certain environmental factors limit it. The major limiting factor is that southern and eastern areas of the Levant are

an extreme desert that, for many animals, is too hostile a habitat for survival.

Historic Zoogeography

Levantine biota constitute one of the most complex ecosystems in the world: Ethiopian and Oriental taxa coexist with Euro-Siberian, central Asiatic, and Mediterranean species, mixed with Saharan and Arabian desert faunal elements. This kaleidoscopic admixture of Palearctic, Paleotropical, and Saharo-Arabian elements has been constantly changing during the Neogene and the Quaternary periods, disposing a new biogeographic configuration during each geological period. Consequently, the Recent fauna is a living monument to a fascinating animal history and ecology. Current zoogeographic patterns in the Levant are the result of four major formative events (Por, 1975; Tchernov, 1988):

1. The breakup of the Tethys Sea during the Miocene and the consequent establishment of the Eurasian-African land bridge: Approximately 18–24 million years ago (late Oligocene–early Miocene) northern regions of today's Levant were still under the large Tethys Sea, whereas southern regions were terrestrial and part of the vast Afro-Arabian continent, with its unique faunal realm (Figure 2). Approximately 17 million years ago (Ma) the Tethys contracted, the emerging lands combined the southeastern areas of Asia Minor with the northwestern areas of Arabia, and the Levant was formed (Figure 3).

Figure 2 Paleographic map, 20 Ma. The Tethys is connected with the Indian Ocean, thereby separating Afro-Arabia from Eurasia (the Levant is represented by the rectangle). The southern Levant is part of the Afro-Arabian domain, and other parts are submerged (adapted from Tchernov E (1988) The palaeobiogeographical history of the southern Levant. In: Yom-Tov Y and Tchernov E (eds.) *The Zoogeography of Israel*. Dordrecht: Junk). Reprinted with permission from Springer.

Figure 3 Paleographic map, 10 Ma. The Tethys is no longer connected with the Indian Ocean. In the north, extensive land connections with Eurasia enable the invasion of Palearctic elements into the Levant. In the south, land connections with Africa gradually break up due to the development of the Red Sea (adapted from Tchernov E (1988) The palaeobiogeographical history of the southern Levant. In: Yom-Tov Y and Tchernov E (eds.) *The Zoogeography of Israel*. Dordrecht: Junk). Reprinted with permission from Springer.

Bridging the two continents, the newly formed Levant triggered an interchange of terrestrial biota between Africa and Eurasia. A wide spectrum of habitats were present in the Levant during much of the Miocene, including rivers, lakes, marshy habitats, dense woods, and Palearctic rain forest, together with open country.

Early Miocene deposits in the southern Levant contain a diverse community of animal taxa, most of which were of African origin (proboscoideans, crocodiles, soft-shelled turtles, and catfish) but with others representing Eurasian elements (viverrines and cricetines). It seems that during this period African forms found it relatively easy to emigrate into the Levant, whereas contemporaneous Eurasian forms found it more difficult.

2. The late Miocene and Pliocene drying out of the Old World subtropics and the formation of the vast belt of the Saharo-Arabo-Syrian deserts, which restrained terrestrial migration between Africa and the Levant: The desertification process was very gradual. At first, approximately 12–15 Ma, open-land biota of savanna and semisteppe began to expand, and in doing so they created an extremely diversified mosaic of biotopes that ranged from the East African highlands through (still connected) Arabia to the Levant and enabled large-scale biotic interchange. Gradually, however, aridity along the Saharo-Arabian latitudes increased (associated with intensification of seasonality) so that by approximately 5.5–6 Ma (late Miocene) a vast arid belt of almost continental size formed which became a severe biogeographic barrier. Eventually, this desert barrier was settled by strongly eremic-adaptive species recruited from its immediate surroundings. The desert fauna of the Levant thus originates from both Eurasia and Africa and is established along adaptive rather than historical lines. It is more between than within faunal realms.
3. Quasi-isolation and biogeographical provincialism of the Levant during the Pliocene: Beginning approximately 5 Ma three geomorphological events had profound effects on the biota of the Levant. To the north, orogeny of the Taurus-Zagros mountain chains restrained many northern Palearctic elements from migrating southwards. To the south, the Red Sea opened up (Figure 4) and connected with the Indian Ocean, thereby establishing, for the terrestrial fauna, a marine barrier between Africa and the Levant (in addition to the already existing desert). The third event was the brief flooding of the Mediterranean by oceanic waters through the Gibraltar straight. All along the Levant coastal plains were submerged, and deep marine embayments penetrated into such lowlands of the Levant as (today's) Dead Sea Rift Valley and Plain of Beer-Sheva (Figure 5). These marine embayments of the Mediterranean (which gradually retreated later in the Pliocene) formed biogeographic barriers that enabled local speciation.

Pliocene mammals of the Levant (from a site near Bethlehem) are of open-country species, suggesting a lowland African savanna-like landscape, with some freshwater bodies nearby. The absence of deer, beavers, dormice, and bears (common in the Pliocene of Turkey) is noteworthy.
4. The successive creation of the Jordan-Orontes rift valley in the late Pliocene and early Pleistocene: During the Plio-Pleistocene transition (approximately 1.8 Ma) large-scale tectonism occurred in the southern Levant, which established a longitudinal geomorphological feature that opened initially in the south and gradually northward. The Jordan-Orontes valleys, with their chains of lakes and swamps, were then created, the cis- and trans-rift mountain ranges were then lifted, and basalts were extruded in the

Figure 4 Paleogeographical map, 5 Ma. The marine connection established between the Red Sea and Indian Ocean results in relative isolation of the Levant from Africa (adapted from Tchernov E (1988) The palaeobiogeographical history of the southern Levant. In: Yom-Tov Y and Tchernov E (eds.) *The Zoogeography of Israel*. Dordrecht: Junk). Reprinted with permission from Springer.

eastern regions of the Levant. It was during the Pliocene–Pleistocene that the contemporary relief structure of the Levant was molded (Por, 1975; Tchernov, 1988).

Levantine faunas during the lower Pleistocene were characterized by a bloom of Palearctic elements and a deterioration of tropical ones, suggesting that the Zagros Mountains filter barrier had by then been overcome and that the Saharo-Arabian barrier, between the Levant and Africa, had already become highly effective (Tchernov, 1988). By 1.4 Ma, two-thirds of the mammal genera (from a site in the Jordan Valley) were of Eurasian origin. The remaining one-third were mainly of tropical origin, and many African mammals entrapped in the Levant underwent local speciation (*Hippopotamus behemoth*, *Praomys minor*, and *Arvicanthis ectos*). By the mid-Pleistocene (800,000–150,000 years ago) additional Palearctic immigrants had invaded the Levant (squirrel, hare, Syrian bear, and wild cat), various tropical elements had become extinct (giraffe, monkeys, the fossil artiodactyls *Pelorovis* and *Kolpochoerus*), and there were no further massive invasions of tropical elements; the fauna was becoming similar to that of today. From 125,000 years ago onwards (upper Pleistocene) there were no drastic changes in faunal turnover rates. In many species of snails, voles, mole-rats, wolves, bear, and gazelle, however, there were considerable changes in body size to adjust to environmental fluctuations. These size alterations suggest that Pleistocene climatic changes in the Levant affected population levels more than species extinctions (Heller, 1988; Tchernov, 1988).

Today, the majority of animal genera in the Levant (more than three-fourths) occur outside the Levant exclusively to the north or northeast. Faunal connections with Eurasia are thus obvious. The extent of the Eurasian element varies from group to group. Almost all species of land snails are of Palearctic origin, as are three-fourths of the fruit flies (Tephritidae), two-thirds of the butterflies, and one-fifth of all chironomids.

Figure 5 Paleogeographical map, 4–5 Ma. Marine ingress of the Mediterranean into the newly formed Jordan–Dead Sea Rift Valley brings marine elements into the Jordan Valley (adapted from Tchernov E (1988) The palaeobiogeographical history of the southern Levant. In: Yom-Tov Y and Tchernov E (eds.) *The Zoogeography of Israel*. Dordrecht: Junk, based on Bernor (1987), Gvirtzman and Buchbinder (1977, 1978), and Rögl and Steiner (1983)).

Furthermore, the extent of the Eurasian element within each group may vary from one region of the Levant to another. From Mt. Hermon to Sinai frequencies of Palearctic butterflies decrease from 88 to 43%; within the Palearctic ant genus *Formica*, the number of species decreases from Turkey (12) through Lebanon (1) to Israel (absent; Kugler, 1988; Benyamini, 1988; Heller, 1988).

Tropical elements comprise approximately 5–15% of the fauna, but again this varies from group to group. Approximately 12% of the ant species are tropical or have strong tropical affinities; Diptera (in general) comprise approximately 5–10%, chironomids 40%, land snails 1%, and there are no aquatic oligochaetes. Within the Levant, tropical components in butterflies increase from approximately 8% on Mt. Hermon to 32% in Sinai.

Although most tropical elements are either Ethiopian or Palearctic, a small Oriental element is also present (Table 2). This is noteworthy because the Orient is distant from the Levant and separated from it by a vast desert barrier. The influence of the Oriental species is sporadic and does not reach

sizable percentages in the whole fauna. Freshwater fishes and aquatic insects are exceptions, however.

In conclusion, the Levantine land bridge serves as an important crossroads of biotic exchange. Along the tropical wet and savanna-like landscapes of the rift valley, African animals entered Palearctis. Along the Mediterranean woodland and dry steppe landscapes of the bordering mountains, Eurasian animals invaded Africa. Among the dunes of the shoreland, eremic, Saharan biota advanced northward. The Levant thus functions as a complex biogeographic corridor in which representative species of the Ethiopian, Palearctic, and even Oriental biogeographic realms are encountered side by side. This mixture of faunas is outstanding and perhaps unique.

Endemic versus Widespread Animals

The Levant is characterized by the high frequency of marginal populations of species which range beyond the Levant. However, it is also rich in endemics (Table 3). Endemism is a function of a group's low mobility, combined with its tendency to speciate. It is therefore not surprising that within the vertebrates, endemism is higher among (the more sedentary) fish and reptiles of the Levant than among (the more mobile) mammals and birds; within arthropods it is higher among

(the more sedentary) ants than among the (highly mobile) butterflies and wasps.

Comparisons within and between groups should not be carried too far, but the very high extent of endemism among land snails is noteworthy. This may be because they are, as a whole, very ineffective in crossing even minor ecological barriers of substratum or aridity. Consequently, many land snail species of the Levant have a very small range, sometimes only a few square kilometers. The endemic enid *Pene galilaea* is confined to a very small area of approximately 1.5×2.5 km in northwestern Upper Galilee, where it is surrounded by another species, *P. sidoniensis* (Figures 6 and 7); also, the endemic hygromiine *Trochoidea picardi* is confined to an area of 3×5 km in the coastal plain, where it is completely surrounded by *T. davidiana*. Similarly, the high level of endemism among bushcrickets is probably due to limited dispersal ability due to their loss of ability to fly. Approximately 45% of the Israeli bushcricket species are brachy- or micropterous, and 84% of these flightless species are endemic compared to 13% of the fully winged flying species.

It is tempting to seek "hot spot" regions, in which the extent of endemism is high and cuts across many animal groups. For the Levant, it is difficult to single out such regions. Endemics occur in many different regions.

In contrast to the endemics, several genera of the Levant enjoy an incredibly wide, intercontinental distribution. The

Table 3 Endemism among groups of the Levant or regions of it

Animal group	Endemic species	Reference
Dragonflies (Odonata)	One-third	Dumont (1991)
Termites (Isoptera)	One-third	Kugler (1988)
Bushcrickets (Tettigonidae)	Half	Ayal <i>et al.</i> (1999)
Flies; asilids (Asilidae)	Half	Theodor (1980)
Butterflies	None, or negligible	Benyamini (1988)
Caddisflies (Trichoptera)	Two-fifths	Botosaneanu (1992)
Wasps (Vespidae)	None	Kugler (1988)
Ants (Formicidae)	One-fourth	Kugler (1988)
Land snails (Pulmonata)	Two-thirds	Heller (1988)
Fish (Pisces)	One-fourth	D. Golani (personal communication)
Reptiles and Anurans	One-tenth	Werner (1988)
Birds (Aves)	None, or negligible	Yom Tov (1988)
Mammals (Mammalia)	~2%	

Figure 6 Narrow-ranged endemism in the Levant: total global distribution of the land snail *Pene galilaea* (▲) is only 8 km² in the western Galilee (○, sites of *P. sidoniensis*) (adapted from Heller, 1993). Reprinted with permission from Springer.

land snail genera *Truncatellina*, *Lauria*, *Cecilioides*, and *Punctum*, minute snails of the litter or subterranean environment, are found outside the Levant not only throughout Eurasia but also in much of the African continent. *Oxyloma*, an amphibious genus that lives on the vegetation above water, is also included in this list. All these taxa probably reached the Levant by aerial dispersal that, whether by wind or by birds, puts a premium on small size and light weight.

Aerial dispersal separates these widespread animals from many genera of Palearctic origin, which migrated into the Levant by the diffused, gradual movement of populations across hospitable terrain over many generations. It enables constant colonization. In the Levant, for land snails, birds are probably a more important aerial transporter than the wind. They migrate very regularly over considerable distances and are large enough for the accidental transport of minute animals without inconvenience. Birds migrating from Eurasia to Africa via the Levant could thus be responsible for at least some of the minute fauna of the Levant.

Figure 7 Wide-ranged distribution in the Levant: *P. sidoniensis* ranges over ca. 1200 km² in the southern Levant alone; it also occurs in the northern Levant and southern Turkey (adapted from Heller, 1993). Reprinted with permission from Springer.

Factors Determining Diversity

Diversity fluctuates considerably in the different geographic regions of the Levant. The following sections focus on rain and substratum, the major physical environmental forces that, by determining distribution, influence diversity; and on vegetation, an important biotic factor.

Rain

The Levant is situated on the margin of the extreme desert and the mean annual rainfall decreases from 1000 mm to less than 100 mm over the short distance of 150 km. This sharp gradient is reflected in animal ranges, with borderlines coinciding with isohyets so closely that there can be little doubt that rainfall is a major factor and of paramount importance in regulating animal distributions (Figure 8).

In rain-regulated distributions the species are classified into two categories: allopatric and parapatric. Allopatric species do not share borders with any other species of their genus. The dependence of such a species' range on rain, directly or indirectly, seems unequivocal. (For example, the Mediterranean-dwelling snails *Paramastus episomus* and *Pene sidoniensis* are the southernmost species of their genera. *Paramastus episomus* does not range below the 500-mm isohyet and *P. sidoniensis* not below the 400-mm isohyet.) Parapatric species pairs, on the other hand, share a common border of distribution. The location of the frontier within such pairs may well be influenced by interspecific competition, and rain could simply be the factor determining the point of equilibrium between the species (*Sphincterochila cariosa* and *S. fimbriata*, on the 500-mm isohyet, exemplify this group).

In many groups, overall biodiversity is a function of the amount of rain. In this context, the 200-mm isohyet, representing the end of the Mediterranean and the beginning of the desert landscape, appears to represent a barrier that many animal species cannot cross. In the Negev and Judean Deserts (areas receiving less than 200 mm of rain annually) only 25 land snail species are found compared to 73 species in the Mediterranean landscape. Of these 25 desert species, 7 occur in both the desert and the Mediterranean habitats. A generally similar pattern occurs at the generic level: Only 10 genera are recorded from the deserts of the Levant compared to 40 genera in the Mediterranean landscape; of these 10 desert genera, 8 occur in both desert and Mediterranean landscape and only 2 occur exclusively in desert areas. These comparative data indicate that adaptations to desert conditions are generally restricted to the species level rather than to higher taxonomic categories.

A similar trend of decrease in diversity also occurs among dipteran families (Table 4). In four latitudinal sections of Israel that broadly represent a decreasing gradient in rainfall, Freidberg (1988) noted that of 77 families, 20 were progressively restricted to the more northern sections, with 2 families occurring only in the extreme north. Only 57 families were detected from all four sections.

Among arachnids, the 350-mm isohyet (rather than the 200-mm one) demarcates the end of the Mediterranean and beginning of the desert fauna.

Figure 8 Distribution patterns that correlate with rain: The land snail *Eopolita protensa* is delimited by the 400-mm isohyete. Each dot represents all samples collected within a 5 × 5 km area (adapted from Heller, 1993). Reprinted with permission from Springer.

Studies of species distributions along climatic gradients may aid in predicting potential faunal responses to global climatic change. However, although a "univariate" approach in which a separate model is constructed for each species is more accurate than a multivariate one, it is not very efficient for analyzing climatic responses of large species assemblages or high taxonomic groups. However, scaling up from the level of individual species to higher taxonomic levels is crucial for evaluating faunal responses to global climatic change. Early suggestions (Heller, 1988) that rainfall is important in determining patterns of land snail diversity in Israel were based on nonquantified generalizations deduced from distribution maps of single species. Recent research (Kadmon and Heller, 1998) analyzes the response of the entire land snail fauna of Israel to gradients in mean annual rainfall by integrating

Table 4 Occurrence of diptera families in latitudinal sections of Israel

Latitudinal section	No. of families common to various latitudinal sections				Total no. of families
	A–D	A–C	A–B	A	
A (N of 33°)	57	10	8	2	77
B (32–33°)	57	10	8	—	75
C (31–32°)	57	10	—	—	67
D (S of 31°)	57	—	—	—	57

geographical information system (GIS) tools and standard multivariate techniques. Faunal variation of land snails was found to be significantly correlated with underlying variation in rainfall (as expected), but the effect of rainfall on the fauna was much greater in drier regions than in more rainy areas. Above 450 mm, no relationships could be detected between the patterns of faunal variation and rainfall.

Adaptations to Dry Conditions

Many desert species of the Levant differ from closely related Mediterranean species, or subspecies or populations, in their physiological adaptations to stress (Shkolnick, 1988). In the harsh environment of the desert, shortage of water and scarcity of adequate food are the major factors that pose a threat to many animals. I briefly discuss the various strategies that land snails and mammals employ to overcome these threats.

Concerning water economy, important adaptive features in determining a snail's ability to inhabit dry deserts include not merely resistance to desiccation but also instant adjustment of the rate of water loss to oncoming desiccation. Within the snail genus *Sphincterochila* (Sphincterochilidae), desert-dwelling *S. zonata* is capable of immediate response to desiccating conditions compared to Mediterranean species that take 3 or 4 days to recruit their water-preserving mechanisms; the steppe-dwelling species *S. fimbriata* is intermediate in its speed of adjustment (Arad *et al.*, 1989). A similar picture emerges among hygromiid and helioid land snails of the Levant. Desert-dwelling *Trochoidea simulata* and steppe-dwelling *Xeropicta vestalis* respond rapidly to desiccation, whereas the Mediterranean *Theba pisana* and *Monacha haifaensis* require up to 4 days to adjust their rate of water loss (Arad *et al.*, 1992).

Barriers to water loss in land snails of Levantine deserts include the shell; consequently, land snails in which the shell is missing, internal, reduced to a small external remnant, or without considerable calcium enforcement do not enter the desert of the Levant (*Limax*, *Limacus*, *Milax*, *Deroceras*, *Daudebardia*, *Eopolita*, *Oxychilus*, *Vitrea*, and *Oxyloma*). The epiphragm (a mucous-calcareous sheet spread over the shell aperture during seasons of inactivity) is also an important barrier to water loss, and *S. zonata* has the thickest epiphragm and also lower water loss than the Mediterranean species of *Sphincterochila*. Another adaptation is the extrabody water reservoir that snails carry inside their shell: Species that lose significant amounts of water during desiccation do so almost equally from both body and extrabody compartments. However, in desert species the water content of the body is more

closely controlled at the expense of extrabody water, thereby avoiding severe dehydration of soft body tissue.

Superiority in resistance to desiccation, however, is not always unique to desert animals. Mediterranean-dwelling *X. vestalis* enjoy a water loss of only 0.13% per day and cope better with desiccation than do desert-dwelling *T. simulata* (Arad, 1990). However, *X. vestalis* is a semelparous, annual species. It cannot survive even one single rainless year in the desert since all the populations would be wiped out in such an event. *Trochoidea simulata*, with somewhat less efficient mechanisms, reaches a life span of at least 3 years and can survive a rainless year (Heller, 1988; Arad, 1990).

Furthermore, within the genus *Sphincterochila*, desert-dwelling *S. prophetarum* has water regulatory capacities similar to those of the Mediterranean species of this genus. *Sphincterochila prophetarum* dwells underneath stones, where humidity is high compared to other microhabitats of the Levantine desert.

Desert snails of the Levant, to conclude, are adapted to withstand desiccation stress in that they usually have lower and slower rates of water loss and are capable of closer regulation of stable water content of the body compared to Mediterranean snails.

Desert mammals of the Levant differ from Mediterranean mammals in that they have a lower energy metabolism. Among murid rodents of Mediterranean landscapes, *Apodemus sylvaticus* and *A. mystacinus* possess the basic metabolic rate as expected from their body mass (according to the "mouse to elephant curve"). However, in the common spiny mouse *Acomys cahirinus*, a species of both Mediterranean and desert habitats, this rate is only 75% of the expected value, and in the golden spiny mouse *A. russatus*, a species of the extreme desert and regularly active during the day, it is only 55%. Similar comparative patterns have been found among gerbils, hedgehogs, carnivores, and ruminants of the Levant. A low metabolic rate, implying a lower rate of heat generation, saves the water otherwise needed to dissipate heat in a hot environment (Shkolnick, 1988).

In addition to a shortage of water, food in the desert is also at a premium. The frugal food requirements of desert animals may be related not just to a low demand for metabolizable energy. An efficient digestion of the food consumed may also reduce the amount of food required for maintenance. Desert mammals require less food for their maintenance than do nondesert ones. Bedouin goats herded in the southern Levant consume less food, retain it in the gut for a longer time, and digest it more efficiently than do European breeds of goat,

thereby gaining more energy from a given mass of food. In addition, the Bedouin goat has a remarkably spacious rumen, which functions not only as a fermentation vat but also as a voluminous water reservoir, enabling the goat to graze in the water-depleted desert without depending on frequent drinking (Shkolnick, 1988).

Balancing their nitrogen metabolism is as much a challenge for desert mammals as the maintenance of a balanced energy metabolism. The camel, instead of wasting the nitrogenous end products of protein catabolism, first retains them in its kidney and later allows them to be recycled through the gut. Here, the urea and other nitrogenous wastes are used by the microbial symbiotic population for resynthesis of protein, from which the host animal will eventually benefit. The potential capacity for recycling urea is far greater in desert than in Mediterranean species. Recycling of urea, in addition to helping the animal survive on low-protein feed, attenuates the load on the water otherwise required for the elimination of that waste (Shkolnick, 1988).

In conclusion, rain is the major environmental factor determining the diversity of animals within the Levant. The (approximately) 200-mm isohyet marks the arid limit beyond which many species of the Levant cannot exist.

Substratum

Within the boundaries of the relevant isohyets, animal distribution is further limited by lithic factors: The checkered geomorphologic map of the Levant presents a wide range of substrata, including granite, basalt, limestone, chalk, marl, heavy alluvium, calcareous sandstone, and light sand dunes.

Calcium-rich environments are very abundant in the Levant. Concerning one particular animal group, land snails, the abundance of limestone, chalk, or calcium-rich soils derived from them is a prerequisite for the flourishing of any testaceous fauna. Acid environments, which restrict the diversity in many regions of Europe and which in many evergreen forests throughout the world exist due to the gradual addition of acidic elements to the litter, are not known to exist in the Levant to any sizable extent. Granite and basalt, from which the extraction of calcium is difficult, are restricted to small areas. This lithic composition is an important reason for the high diversity of land snails in the Levant.

In some cases, the distribution of land snails varies in close association with geomorphology. The endemic *Cristataria genezarethana* occurs almost exclusively on mid-Eocene formations and is absent from nearby lower Eocene ones. Both formations consist of calcium, but only the mid-Eocene rocks are rich in crevices, which *C. genezarethana* inhabits (Figure 9). However, among many groups, only two major categories of substratum-dependent groups can be distinguished: the fauna of the limestone mountains and that of the loose sands. Limestone mountains in the Levant are the substratum that is richest and most diverse in species because they produce a rich mosaic of habitats and provide many shelter niches. Complex systems of rock crevices, moderately dense litter, soil pockets, generous vegetation cover, and a variety of exposed versus shaded sites are all to be found on limestone but not always on other substrata. Accordingly, a 100 × 100 m of limestone in

Figure 9 Distribution patterns that correlate with substratum: The land snail *Cristataria genezarethana* is restricted to the mid-Eocene formation (squares) and absent from the lower Eocene formation (lines). ●, Sites in which snails were found; ○, sites in which they were not found (adapted from Heller, 1993). Reprinted with permission from Springer.

the Judean Hills (in a Mediterranean landscape that receives approximately 570 mm of rain annually) yields 15 species of snails. A similar nearby area consisting of chalk, marl, or alluvium produces only 4 species, all of which also occur on limestone. Chalk, marl, or alluvium merely contain an impoverished, depauperated element of the rich limestone fauna but without any characteristic component of their own. Crevices provide shelter from the severe heat and drought prevailing throughout the summer. Whereas limestone has a well-developed system of crevices, chalkstone, marl, and alluvium do not and therefore, presumably, crevice dwellers cannot inhabit them. Also, the rich assemblage of litter habits, inhabited mainly by small invertebrates, is often well developed in limestone but nonexistent in nearby chalk or marl. Accordingly, there are no litter dwellers in such substrata. Extensive alluvial plains, such as Yizre'el, Zevulun, or the hinter parts of the Levant's coastal plain, harbor little diversity.

Sands of the Levant contain a fauna that differs considerably from that of the nearby calcareous mountains and alluvial soils (Kadmon and Heller, 1998). Furthermore, sands of the Mediterranean climatic region may differ from those of the Negev (Figure 10), which is arid.

Figure 10 Distribution patterns that correlate with substratum: Land snails restricted to sand. *Theba pisana* (●) occurs in sands of more northern, Mediterranean climatic regions, whereas *Eremina desertorum* (▲) occurs in the more southern sands of the Negev. Each dot represents all samples collected within a 5 × 5 km area (adapted from Heller, 1993). Reprinted with permission from Springer.

Adaptations to Sand

Sand differs from other substrata in its “near-fluid” texture, which makes locomotion and burrowing more difficult than in other habitats. However, it holds more water than many other substrates so that more water is eventually translated into a more productive biotic community.

Many taxa of the animals restricted to sands converge in their morphological adaptations, thereby signifying the importance of sand as an evolutionary agent. Among reptiles of the Levant, a suite of morphological, physiological, and behavioral adaptations enables certain taxa to live in the sands or endows them with a competitive advantage (Werner, 1985). Locomotion over sand is facilitated in lizards by expansion of the feet. In *Acanthodactylus*, the extent of fringing along the toes varies with the looseness of the substrate intraspecifically and interspecifically (Figure 11A). Also, the toes of the gecko *Stenodactylus* spp. are fringed, and those of the skink *Scincus scincus* are flatly expanded (Figure 11B). Sand-dwelling viviperids locomote by sidewinding, as do *Cerastes* spp. and *Pseudocerastes fieldi*. *Lytorhynchus diadema* employs a unique variety of serpentine locomotion mechanisms wherein the loops push the sand down rather than sideways. Since burrows tend to collapse, on the one hand, and loose sand enables instantaneous submergence and sand swimming, on the other hand, problems arise from submergence and locomotion within the sand medium. Wedge-shaped snouts, frequent in burrowing reptiles, are prominent in the sand-swimming skinks *S. scincus* (Figure 11B) and *Sphenops sepsoides*. In these and in the snake *Lytorhynchus* the mouth opening is protected from sand during submerged progression by its ventral position. *Lytorhynchus* has an expanded rostral, common but not unique to sand-dwelling snakes. *Cerastes* spp. can submerge stationally by shuffling the flattened body sideways. The vertical flanks of *Scincus* (and *Sphenops*) may improve the lateral thrust during sand swimming. The relatively high species density of Gekkonidae on the sand may reflect the preadaptation of spectacled forms to sand. Breathing below sand is problematical not only at the nasal passage level but also at the thoracic: Upon exhalation the sand caves in and stifles inhalation. *Scincus* and *Sphenops* are structured for breathing with the protected ventral surface angularly set off from the lateral ones (Figure 11B; Werner, 1985).

Figure 11 Some adaptations of Levantine psammophilous reptiles to sand. (A) Foot of *Acanthodactylus schreiberi syriacus* showing fringe of spiny scales along third and fourth toes. (B) *Scincus scincus* showing shovel-shaped snout, countersunk jaw, angularly set-off venter, and expanded toes. Photographs printed with permission from Y.L. Werner.

Sand-dwelling scorpions of the Levant can also be distinguished by their morphological adaptations. The most well-known are bristles to aid traction, locomotion, and burrowing in sand. These bristles occur on the tarsomeres and tibiae of all sand-living scorpions. Another leg modification in sand scorpions that acts to increase the effective surface area of the tarsi is long claws (Fet *et al.*, 1998). The bristles and claws create an expanded surface area on the tip of the legs and prevent sinking into the sand. The genus *Buthacus* (represented by *B. arenicola*, *B. yotvatensis*, *B. l. leptochelys*, and *B. l. nitzani*) is a typical sand dweller in the southern Levant, with up to 25 bristles on its walking legs (Levy, 1980).

Sand-dwelling grasshoppers can be distinguished from those of other biotopes by their behavioral adaptations. Sand-dwelling *Hyalorhipis calcarata*, *Leptopternis* spp., and *Eremogryllus hammadae* dig into the sand with their hindlegs, throwing the sand behind them. They are thus able to cover themselves, leaving only the upper part of the head and the antennae exposed above the surface (species of other substrata usually settle "head to sun," thus casting the smallest shadow; Fishelson, 1985).

In conclusion, substratum is the second major environmental factor determining animal diversity in the Levant. Limestone rocks offer calcium, shelter, and an additional microhabitat—that of litter. Sands form a separate substratum category that usually has a unique fauna.

Vegetation

Both animal and plant distribution are influenced by rainfall and substratum, and consequently their distribution patterns may overlap. Whether vegetation influences animal distribution directly, in that different animal species have food preferences for different higher plants, varies among groups. Among fruit flies (Tephritidae), the larvae of practically all species in the southern Levant are phytophagous. All representatives of the Myopitinae, Oedaspidinae, Tephritinae, and Schistopterinae (65–70 species, 25 genera) develop only in plants of the composites (Compositae), whereas none of the Aciurinae and Dacinae do so. The daciine *Dacus oleae* attacks olives (Oleaceae), whereas other daciines are associated with fruits of milkweed (Asclepiaceae). Many tephritid species are oligophagous; a few are polyphagous, using plant hosts of different families. The parts of plants affected by tephritid larvae also vary considerably among groups. Larvae of Dacinae and Trypetinae develop in fleshy or juicy fruits. However, *Euleia heracleii* is a leaf miner, and *Capparimyia savastani* (Figure 12) produces larvae that develop in the flower buds of the caper *Capparis*. Most species of the five subfamilies that attack Asteraceae in Israel develop in fruit heads. The larvae of different species are usually restricted to feeding on certain parts of the flower head, such as flowers, achenes, or the receptaculum. Some species induce the formation of galls (e.g., *Myopites* spp. and *Urophora* spp.). Several species bore into the stems of their hosts, often forming galls (e.g., *Spathulina* spp. and *Oedaspis* spp.). *Orellia falcata*, unlike most members of the Terelliinae, mines along the stem of the goat's beard *Tragopogon* and pupates in the upper part of the root (Freidberg and Kugler, 1989).

Figure 12 Distribution patterns that correlate with vegetation: *Capparimyia savastani* (Tephritidae), the larvae of which develop in flower buds of *Capparis* (reproduced from Freidberg A and Kugler J (1989) *Fauna Palaestina. Insecta 4—Diptera: Tephritidae*. Jerusalem: Israel Academy of Sciences and Humanities).

Some grasshopper species use plants as a food source, resting source, and hideout. Morphological adaptations to this habitat include large arolia to serve for attachment, streamlined and smooth body structures, heads with an acute or subacute angle, long and delicate colorless wings, and usually green or greenish-gray or brown coloration. Behavioral adaptations include resting along branches or stems and, if flying up, moving from plant to plant. When disturbed, many of these species crawl around the stem or branch, remaining on the opposite side to the intruder; others drop from the plant and dig among the dense branches close to the ground. There is a strong correlation between special types of vegetation and their fauna of plant-dwelling acridoids within the Levantine fauna: The Tropicopola–Ochrilidia association of grasshopper species is found on reed *Phragmites*, reed mace *Typha*, and rush *Juncus*; the *Heteracris*–*Eyprepocnemis* association shows a great affinity for knotweed *Polygonum* sp. and wormwood *Artemisia monosperma*; and the *Dociostaurus*–*Morphacris* association occurs mainly in areas with low, usually dry, ephemeral grass (Fishelson, 1985). It is not known if these associations are obligatory.

In contrast to fruit flies, among land snails of the Levant a direct influence of vegetation on diversity is unlikely. Snails feed on a wide spectrum of decaying vegetable matter and saprophytic fungi, occasionally on green tissues, and there is no evidence that food requirements for specific plants determine their wide-scale distribution patterns. Vegetation, however, may play an important role in microgeographic distribution, especially in preventing some snails from occupying certain habitats. Some species of the Mediterranean region (*Buliminus labrosus*, *Sphincterochila cariosa*, *Euchondrus septemdentatus*, *E. saulcyi*, *Paramastus episomus*, and *Xeropicta vestalis*) are found on the southern slopes of hills, where annual vegetation prevails, and are very uncommon on the northern slopes that are covered with dense oak maquis. In regions in which the vegetational distinction between northern and southern slopes is not obvious, the distinction of the snails between the slopes also becomes obscure, and they also occupy the northern slopes. A preference for the south slopes could perhaps be due to the annual vegetation prevailing on

it. Annual plants do not develop xeromorphic characters and are therefore easily eaten and digested. The oak maquis of the north-facing slope may be cool and damp and offer more shelter, but it consists mainly of perennial vegetation. The development of xeromorphic characters (such as the thick cuticle of the oak leaves) necessary for plant survival in the dry season could perhaps be an obstacle for snail feeding and digestion. Too little information is available on the precise diet of many animal groups. Once this information is gained, I believe that a major breakthrough will occur in our understanding of biodiversity in the Levant.

Freshwater Diversity: Historic Factors

The inland water system of the Levant is dominated by the north–south-oriented topography of the Rift Valley. The three major rivers of the Rift (the Jordan, Litani, and Orontes) run along successive segments of the valley and create a “steep chase” waterway. Between the Rift basin and the Mesopotamian basin, watershed shifting and headwater capture may well have enabled a faunal transition of transcontinental dimensions.

During the Pliocene the Mediterranean flooded the southern Rift Valley and upon its retreat it left, in the freshwater of the Jordan Valley, several marine relicts. Crustacean species of the Jordan Valley suggested by Por (1975) as marine relicts of the Pliocene invasion include *Loxoconcha galilea*, *Pseudobradia barroisi*, *Nitocra balnearia*, *Monodella relicta*, *Typhlocirolana reichi*, *Typhlocaris galilea*, and *Bogidiella hebraea*. The blind prawn *Typhlocaris galilea* (Figure 13) is endemic to a subterranean warm, sulfide-rich spring near the shores of Lake Kinneret, where it feeds on oligochaetes (*Isochaeta israelis*) and snails (*Theodoxus jordani*).

From the Pleistocene onwards there was a continuous existence of freshwater or saline lakes in the Jordan Rift Valley. In this large endorheic system, the smallest climatic change and the changing balance of evaporation and precipitation (in addition to any slight tectonic movement) resulted in considerable fluctuations of water levels, with the creation, fusion, separation, and disappearance of lakes and rivers. This resulted in richly diverse faunas that partly replaced one another throughout the Pleistocene. Some old lacustrine freshwater endemics have survived in the Jordan system since the early Pleistocene (Table 5).

The fish fauna of the Levant is a mixture of Palearctic, Oriental, and Ethiopian species. Thirty-four species of freshwater fishes occur in the Orontes, the largest river of the Levant. Of these, approximately two-thirds are Palearctic, one-third are Oriental, and only 3% are African elements. The Orontes shares 18 of its species with the Tigris–Euphrates but only 7 with the Jordan River. The number of species occurring in the Jordan, the second largest river, is only slightly lower, but the species composition is totally different: Of 28 species, the Palearctic, Oriental, and African elements each comprise about one-third. The Jordan River shares only 3 species with the Tigris–Euphrates, but 6 additional species have their closest relatives in Mesopotamia. Apparently, the Jordan and various courses of the Orontes were separately colonized via branches of the Mesopotamian river system, and the Jordan

drainage basin became an important center of speciation for several fish lineages with Palearctic affinities. Later, faunal elements of the Jordan reached the Orontes (through the Litani). Some freshwater fish of African origin reached the Jordan Valley by way of freshwater connections to the south. They could have done so up to Pliocene times, and in the Jordan Valley they differentiated specifically or even generically (*Astatotilapia flavijosephi* and *Tristramella* spp.). During later periods, some African fish may have reached the southern Levant from the Nile via the Mediterranean Sea (the euryhaline cichlid *Tilapia zilli* survives well in brackish and even marine waters) (Figure 14). The fish fauna of the Rift's lakes and rivers was thus recruited from the north (Palearctic), east (Euphrates), and south (the Nile; Krupp, 1987).

The headwaters of Jordan constitute a typical temperate Palearctic freshwater fauna, with a “normal” level of diversity that includes pulmonate snails, cold-water copepods, and

Figure 14 Cichlids of the Levant: *Tristramella sacra*, an endemic genus of African origin; *Astatotilapia flavijosephi*, an endemic species of African origin; and *Tilapia zilli*, an African species that may have reached the Levant via the Nile and Mediterranean Sea (reproduced from Lortet (1883) Etudes Zoologiques sur la Faune au Lac de Tiberiade, Part I. Arch. Mus. d'Histoire Nat. 3, 99–194, Lyon, France).

many stream-living insects such as stone flies (Plecoptera), Elmidae among the Coleoptera, and typically cold-water-like *Rhyacophila* (Trichoptera). There are no less than 12 species of caddis flies (Trichoptera) in the springs of the River Dan; there are 13 species of Ephemeroptera in the River Hatzbani.

Elsewhere in the southern Levant, there is little of this rich freshwater fauna. In all the springs and brooks of Israel, usually only two species of Ephemeroptera can be found, *Cloeon dipterum* and *Caenis macrura*, which are well-known for their broad ecological valency. Only a small number of freshwater invertebrates are found in every spring and brook. This is a monotonous fauna characterized by *Melanopsis buccinoidea* (Mollusca), *Proasellus coaxalis*, *Echinogammarus syriacus* and *Eucyclops serrulatus* (Crustacea), and *Dina lineata* (Hirudinea).

However, even this impoverished fauna does not advance much further than the oasis springs of En Avdat and of Qadesh Barnea, on the brink of the extreme desert. In most springs of Sinai, usually only insects or passively transported animals occur (Por, 1975).

Biodiversity: The Human Impact

Since the dawn of the Pleistocene, the Levant has been inhabited by the evolving hominids, starting with the early *Homo erectus* of the Jordan Valley. It was in the Levant that the 10,000-year-old Neolithic revolution of the Old World, with its agriculture and animal domestication, occurred.

The history of the Levant is characterized by tides of highly sophisticated agricultural civilization and ebbs of nomadic destruction. Agricultural apogees saw the development of soil protection, terracing, aqueduct and irrigation works, and drainage of swamps, whereas nomadism brought erosion, overgrazing, destruction of irrigation works, and swamping. Nomads semiconsciously created the deserts, of which they are often called the sons. Throughout history there was a progressive destruction of the woodland habitats by ever-increasing deforestation.

However, the most profound effects of man on biodiversity of the Levant started at the beginning of the twentieth century with the tremendous increase in human populations, use of firearms, extent of cultivated areas, and use of pesticides. These changes have had a pronounced, and in many cases fatal, effect on wildlife in the Levant. The effects of various human activities on animal life in the Levant (mainly in Israel and mainly concerning vertebrates) have been studied in depth by Yom-Tov and Mendelssohn (1988).

Hunting

The proliferation of firearms into the Levant by the end of the nineteenth century was followed by the overhunting and extermination of many game animals, mainly at the beginning of the twentieth century. Roe deer *Capreolus capreolus* and fallow deer *Dama dama mesopotamica* used to occur in the woods of Galilee and of Mt. Carmel; the last roe deer was shot in approximately 1912 and the last fallow deer probably at the beginning of the twentieth century. Oryx *Oryx leucoryx* still lived in Jordan at the beginning of the twentieth century; the last were shot before 1950. The last onagers *Equus hemionus hemippus* survived in the Syrian desert until the early 1930s. The bear *Ursus arctos syriacus*, which used to live near the Sea of Galilee and on the slopes of Mt. Hermon, was shot to extinction during World War I. The last cheetah *Acinonyx jubatus* in Jordan was shot in 1962. Two leopard subspecies existed in the Levant. The northern one, *Panthera pardus tulliana*, used to be found in Turkey, Lebanon, and Syria and was not rare in the Galilee at the beginning of the twentieth century; the last individual was killed in 1965, and today this subspecies is extinct. The other subspecies, P.p. *nimr*, survives in the Judean desert and Negev. An ostrich (*Struthio camelus syriacus*) was seen in Jordan in 1932; now this species is extinct in the Levant. The Nile crocodile *Crocodylus niloticus* was found in swamps near Mt. Carmel as late as 1912 (Yom-Tov and Mendelssohn, 1988).

Hunting also caused the almost total elimination of the green and loggerhead turtles (*Chelonia mydas* and *Caretta caretta*) which used to nest along the sandy Mediterranean beaches. During 1920–1930 approximately 30,000 turtles were killed along Israel's seashores; in 1985 only 14 nests were found along its whole Mediterranean coast.

Today, effects of hunting on wildlife in the Levant vary in broad correlation to the enforcement of hunting laws (and hence to political borders). In Israel, hunting today has only minor effects. There are only approximately 5000 licensed hunters and the main game species are chuckar partridges, rock pigeons, doves, various wintering waterfowl, hare, porcupine, wild boar, and mountain gazelle where they damage agricultural crops.

Many of these may be hunted only during well-defined seasons, and none are seriously affected by hunting. Indeed, increasingly efficient enforcement of hunting laws has enabled several species to recover: the leopard *Panthera pardus nimr*, of which approximately 20 individuals now dwell in the Judean Desert and Negev; the wolf *Canis lupus pallipes*; and the hyena *Hyaena hyaena*. All wild mammals, birds, and mollusks in Israel are completely protected by law, with the exception of designated pest species (rats, house mice, voles, fruit bats, house sparrows, etc.).

Habitat Destruction

Most habitats of the Levant have been severely or completely destroyed by urban and agricultural development. Two examples are presented in the following sections (Yom-Tov and Mendelssohn, 1988).

Coastal Sand Dunes

Coastal sand dunes form a narrow strip along the Mediterranean coast of the Levant, and until the beginning of the twentieth century were almost uninhabited by man. Today, however, the majority of the population of Israel lives on the coastal plain. The many urban settlements built on the coastal sands have caused loss of sand dune areas to such considerable extent that of 110 km² of dunes which formerly occurred north of Nahal Soreq, only 3 km² have not been developed.

The land snail *Trochoidea picardi* was an endemic species whose entire small distribution area once ranged over a few kilometers of calcareous sand dune ("kurkar") along the coast of Israel. Today, the entire distribution range of *T. picardi* is buried beneath the motorways, skyscrapers, and residential areas of the Tel Aviv metropolitan area, and this species is almost surely extinct (Figure 15). Concerning nonendemics, the coastal sand dunes are the most eastern extension of Saharan sand-dwelling animals into the Mediterranean, temperate zone of the Levant: the Egyptian tortoise *Testudo kleinmanni*, snakes (*Cerastes vipera*, *Macropododon cucullatus*, and *Lytrochynchus diadema*), skinks (*S. scincus* and *Sphenops sepsoides*), geckos (*Stenodactylus sthenodactylus* and *S. petrii*), lizards (*Acanthodactylus scutellatus* and *Agama savignii*), a monitor (*Varanus griseus*), a chameleon (*Chamaeleo chamaeleon musae*), rodents (*Gerbillus gerbillus*, *G. pyramidum*, and *G. andersoni allenbyi*, the endemic jerboa *Jaculus jaculus schliერი*, and the endemic jird *Meriones sacramenti*), and a hedgehog, *Hemiechinus auritus*. The destruction of the coastal sand dunes (accompanied by predation by feral domestic cats and dogs) has reduced the distribution and abundance of these species.

Wetland Habitats

Wetland habitats that existed in the Levant at the beginning of the twentieth century included swamps, lakes, rivers, springs, and temporary (mainly winter rain) pools; man-made fish ponds were then barely existent. Today, however, water in the Levant is a scarce and much needed resource. All these habitats have been affected.

Swamps

At the beginning of the twentieth century, the Hula swamp ranged more than 40 km² north of the (13 km²) Hula Lake

Figure 15 Extinction due to habitat destruction: total global distribution of the land snail *Trochoidea picardi* (museum records; each dot represents all samples collected within a 5×5 km area). Stippled area, Tel Aviv metropolis, 1999 (adapted from Heller, 1993). Reprinted with permission from Hebrew University of Jerusalem.

(Figure 16) and contained a rich diversity of (mainly wide-spread) animals. The swamp and lake were drained in the 1950s, but a small nature reserve (3 km^2) was created that represents an impoverished version of the original swamp. Even so, 22 species endemic to the Levant have not been recorded from the Hula since its drainage (Table 6). Although the Hula nature reserve is today rich in bird life, eight bird species that once bred in the Hula Valley do not breed there anymore.

Riverine Habitats

The rivers, streams, and wadis in the Levant drain, in general, either to the Mediterranean Sea or to the Rift Valley. Today, most Mediterranean-flowing rivers of the southern Levant are polluted, and consequently most fish have disappeared from them. Gray mullet (*Mugil cephalus* and *M. ramada*) and eel

(*Anguilla anguilla*) fingerlings once used to spend their first years in these rivers (they reproduce in the sea) but now do not occur in most of them. Eight other, entirely freshwater, species are today very rare and the endemic *Acanthobrama telavivensis* now faces extinction. The soft-shelled turtle *Trionyx triunguis*, which once lived in many of the Mediterranean-flowing rivers and nested on their shores, has disappeared from most of them. Only in Alexander River does a breeding population persist, but many of the eggs fail to hatch and the population consists only of very large specimens. The river otter (*Lutra lutra*), a former inhabitant of all these rivers, survives only in the Bezet, Keziv, and Na'aman, in which it is only occasionally seen.

In the Rift Valley-flowing streams the major threat to biodiversity is the extreme reduction in the amount of water that flows in them since most springs are piped by man and used for irrigation. This has reduced and even eliminated the populations of several animal species. The river otter, once common in each major tributary in the Jordan River system, is now rare. The blue-cheeked bee-eater *Merops supecilosus*, which bred along the Jordan River in the early 1930s, does not breed there any more (Yom-Tov and Mendelssohn, 1988).

Temporary Winter Rain Pools

A multitude of temporary winter rain pools once existed in temperate regions of the Levant. Many existed near Arab villages, where their waters once served for watering livestock and for irrigation. Many of these village pools were man-made, built as reservoirs by erecting a dam across a wadi or hewn into rock at the foot of a water-collecting slope, and were probably ancient. These pools supported a rich and varied invertebrate fauna and several species of amphibians.

The number of winter rain pools decreased sharply during the 1960s and 1970s. Many of the formerly undrained valleys were turned into cultivated fields. Other pools were eliminated due to road construction and building. Continuous spraying of herbicides on roadsides and of insecticides on pools near human settlements destroyed this ecosystem or turned these pools into breeding sites for pesticide-resistant mosquito strains. One result of these operations is that the once abundant amphibians have become a threatened group. The spadefoot toad *Pelobates syriacus* (Figure 17) breeds exclusively in rainwater pools and its tadpoles require a long (3 months) development period. Only large seasonal ponds of sufficient duration can support a viable population of spadefoot toads, and only 27 such ponds remain in Israel (including the Golan). Lack of suitable breeding localities has also caused the newt *Triturus vittatus* to become a threatened species, and even the formerly very common tree frog *Hyla arborea* and green toad *Bufo viridis* are becoming rare (Yom-Tov and Mendelssohn, 1988).

Poisoning

More than 700 compounds are registered in Israel's Ministry of Agriculture for agricultural use, including insecticides, acaricides, nematocides, fungicides, herbicides, bactericides, molluskicides, rodenticides, insect attractants, bird and mammal repellents, fumigants, plant growth regulators, and defoliants.

Figure 16 Extinction due to habitat destruction: Lake Hula, now drained (photograph by Kluger). Reproduced with permission from Central Zionist Archives.

Effects of pesticide residues on wildlife started shortly after DDT began to be used at the end of World War II. The most dramatic effect, however, was during the early 1950s, when thallium sulfate-coated grain was widely used to control rodents. These poison campaigns were not necessary. The main damage of these rodents was caused before 1950, when fields were plowed with the traditional shallow-plowing plows that did not disturb rodent burrows. When, after 1950, deep plowing was introduced, rodent burrows were destroyed, the rodents were exposed to predation, and the damage they caused decreased (pest control officers, however, attributed the decrease in rodent damage to their intense poison campaigns). In unplowed areas, as in alfalfa fields, damage caused by voles is still considerable and no rodenticides can prevent it. Since the 1960s, fluoracetamid has replaced thallium sulfate. The residues of both substances accumulate in bodies of secondary consumers such as raptors, bats, and carnivores.

Of 39 species of birds of prey that occurred in Israel before the use of pesticides, all but 2 were seriously affected. Species that once were common breeders became very rare breeders (the black kite *Milvus migrans*, griffon vulture *Gyps fulvus*, long-legged buzzard *Buteo ferox*, Bonelli's eagle *Hieraetus fasciatus*, Egyptian vulture *Neophron percnopterus*, kestrel *Falco tinnunculus*, lesser kestrel *Falco naumanni*, and lanner falcon *Falco biarmicus*). Rare breeders went extinct or their populations decreased drastically (the lapper-faced vulture *Torgos tracheliotus*, spotted eagle *Aquila clanga*, peregrine *Falco peregrinus brookei*, marsh harrier *Circus aeruginosus*, black eagle *Aquila verreauxi*, white-tailed eagle *Haliaeetus albicilla*, bearded vulture lammergeier, and *Gypaetus barbatus*). Thallium sulfate also affected the wintering raptors, whose populations decreased considerably; some species disappeared completely for many years (the sparrowhawk *Accipiter nisus* and merlin *Falco aesalon*). Insect-eating birds, such as lesser kestrel *Falco naumanni* and scops owl *Otus scops*, were perhaps more affected by DDT and other persistent insecticides. The short-toed eagle *Circus*

gallicus remained unaffected, probably due to its specialized reptilian diet and to its absence in winter when most of the poison grain was used. The latter factor also saved the hobby *Falco subbuteo*, the breeding population of which returns to the Levant only in May.

Today, after prohibition of the use of DDT, other chlorinated hydrocarbons, and thallium sulfate, some species have made a comeback but the existing populations of breeding raptors are only a fraction of their former populations. Hundreds of pairs of griffon vulture once bred in Galilee and on Mt. Carmel, but only 20 breed today; only one pair of lapper-faced vultures bred in 1986 in the Negev, where approximately 25 pairs had bred before the widespread use of agricultural poisons began. Continuous breeding attempts by long-legged buzzards, Bonelli's eagle, and golden eagle *Aquila chrysaetus* often fail; only the kestrel seems to have almost fully recovered.

The removal of many raptors had secondary effects on the fauna. The population increase of the blackbird *Turdus merula*, the bulbul *Pycnonotus barbatus*, the palm dove *Streptopelia (Stigmatopelia) senegalensis*, the Syrian woodpecker *Dryobates syriacus*, and the jay *Garrulus glandarius* may be partly attributed to the decrease in the numbers of their predators (mainly the sparrowhawk *A. nisus*).

Secondary poisoning by insecticides also affected some insectivorous birds, particularly species that lived near fields and human settlements. Populations of the swallow *Hirundo rustica*, red-rumped swallow *Hirundo daurica*, white-throat *Sylvia communis*, rufous bushchat *Cercotrichas galactotes*, nubian shrike *Lanius nubicus*, spotted flycatcher *Muscicapa striata*, roller *Coracias garrulus*, bee-eater *Merops apiaster*, and Egyptian nightjar *Caprimulgus aegyptius* all decreased considerably.

Also, insectivorous bats (Microchiroptera) have been affected by chemicals. Twenty-eight species are known in the southern Levant, and many caves used to be inhabited by thousands of roosting bats. The numbers of both

bat-inhabited caves and individuals roosting in them have decreased drastically since the end of the 1950s and most species have become rare. This decline is attributed to two main factors. The first is fumigation of caves with ethylene dibromid and later with lindane (Gammexan). Fumigations were intended to control the fruit-eating bats *Rousettus aegyptiacus*, which were considered fruit pests and which often roost together with insectivorous bats. It was later found that the damage allegedly caused by fruits bats was marginal at best and had been grossly exaggerated by pest control officers. The population of one insectivorous bat, *Pipistellus kuhli*, remained less affected than the others, probably because it roosts not in caves but in hollow trees and in wooden houses. The second

factor affecting insectivorous bats is secondary poisoning: Most bat species occur in the cultivated regions and are highly vulnerable to secondary poisoning because noctuid moths are an important part of their diet. Larvae of noctuids such as *Spodoptera littoralis* are serious agricultural pests, and fields are regularly sprayed with insecticides to eliminate them. Hence, secondary poisoning may be another factor contributing to the decrease of bat populations in the Levant.

The remaining bat populations suffer now from another threat. Increasing numbers of hikers visit various caves and disturb roosting and hibernating bats, thus causing wastage of fat reserves and desiccation of the hibernators.

Carnivores are another group which suffered from poisoning. In 1964, the Plant Protection Department of Israel decided that jackals (*Canis aureus*), one of the few mammals not protected at that time by the "Wild Animals Protection Law," were a nuisance. They were being blamed for damaging plastic sheets used to cover certain crops. A large antijackal campaign was started and tens of thousands of chicks injected with 1081 (fluoracetamid) were spread over the Mediterranean area of Israel in an effort to eradicate the jackals. Several mammal predators were affected, including the jackal, the wolf *Canis lupus*, the red fox *Vulpes vulpes*, the Egyptian mon-goose *Herpestes ichneumon*, the jungle cat *Felis chaus*, and the African wild cat *F. sylvestris*. Most species recovered within a few years and their numbers today are similar to those before the poisoning campaign. The jackal, however, is much slower to recover and its numbers in Israel are still low. The wolf, whose populations in the Negev have increased in recent years due to greater food availability at garbage dumps, is endangered in central and northern Israel, where individuals are larger than those in the Negev and occasionally prey on live-stock. Although the wolf is legally protected, stock owners often retaliate by poisoning.

The caracal *Caracal caracal*, which was formerly known only in the Negev, has increased its distribution area northwards into the Galilee. This range extension coincided with the population decrease in many Mediterranean carnivores following the jackal poisoning operation, suggesting that range extension of the caracal was possible due to the absence of competitors. Apparently, the main competitor of the caracal is the jackal, which preys on hares, the main food item of the caracal. After the jackal poisoning campaign, hares increased considerably. Today, after most predator species have recovered from the effects of poisoning, caracals still occur in the Mediterranean region of Israel but seem to be rare.

Changes in Agricultural Practices

Current agricultural practices in the southern Levant are different from those of the past mainly in that today approximately half of the cultivated area is irrigated. As a result, areas which formerly were left fallow in summer are now cultivated in the dry season.

Some species have responded to the change in agricultural practices with an increase in both abundance and distribution. Population size of the mountain gazelle *Gazella g. gazella* in central and northern Israel increased between 1948 and 1985 from less than 500 to 10,000. Availability of succulent,

Figure 17 Extinction due to habitat destruction: The amphibian *Pelobates syriacus* is now a threatened species because wetland habitats are disappearing (photograph by Y. L. Werner).

nutritious food and of water throughout the year in irrigated agriculture enables female gazelles to deliver their first fawns at the age of 1 year (2 years in nonagricultural areas) and average 1.8 young annually (only 1 in nonagricultural areas). Gazelles have become a pest in several areas because of their high numbers: The males damage fruit trees by rubbing their horns against the bark, and both sexes eat cotton, wheat, corn, and other crops. Increasing food and water availability in agriculture has also affected the dorcas gazelle *G. dorcas* in the southern Negev. Whereas populations near agricultural settlements increased between 1964 and 1985 by 9% annually, the rate of increase in other populations was only approximately 3%. Normally, dorcas gazelles in the southern Levant have only one fawn per year, in spring. Even if this fawn is lost, the dam does not become estrous until the normal breeding season in autumn. In recent years, increasingly more fawns are born in autumn so that either some females breed twice per year, as do mountain gazelles, or females become estrous again after losing their fawn. Autumn fawns are seen mainly near agricultural areas.

Availability of green food in summer and leftover grain in wheat and barley fields has enabled several seed-eating birds to increase their populations to such an extent that they have become agricultural pests: the collared dove *Streptopelia decaocto*, palm dove *Stigmatopelia senegalensis*, house sparrow *Passer domesticus*, and feral domestic pigeons *Columba livia domestica*.

The planting of exotic trees and ornamental plants in human settlements has made new areas available to several bird species. Typical woodland species, such as the syrian woodpecker *D. syriacus*, blackbird *Turdus merula*, great tit *Parus major*, and jay *G. glandarius*, once restricted mainly to woodlands of the Galilee, Mt. Carmel, and Judean hills, are now widespread and common in the gardens and parks that

accompany many human settlements, sometimes even in the Negev and Jordan Valley. The Syrian woodpecker has become a pest in certain areas because it drills holes in irrigation pipes and in telephone cables.

Approximately 1500 plant species, mostly ornamental plants, were imported to Israel during the twentieth century. The orange-tufted sunbird *Nectarinia osea* is favorably affected by this enriched flowering vegetation of ornamental exotic plants in human settlements. When first discovered (in the nineteenth century) it occurred only in the lower Jordan Valley and near the Dead Sea, its distribution coinciding with that of the mistletoe *Loranthus acaciae*. Today, however, owing to the presence of ornamental plants with nectar-bearing flowers, the sunbird is widespread and common in settlements throughout much of the southern Levant.

Another species benefiting from the spread of plantations and gardens is the Arabian bulbul *Pycnonotus barbatus capensis*. It feeds mainly on fruits, flowers, and leaves of introduced plants such as *Melia azedarach*, *Lantana sp.*, *Erythrina sp.*, and other fruit trees and flowers. Due to the ample available food it has increased and become a pest in vineyards and orchards.

Man-constructed fish ponds and water reservoirs present an alternative habitat for some wetland species. The night heron *Nycticorax nycticorax*, little egret *Egretta garzetta*, and to a smaller extent squacco heron *Ardeola ralloides* are the main beneficiaries, but glossy ibis *Plegadis falcinellus* also breed near some reservoirs. All four species were rare breeders or nonbreeders in the Levant until the late 1950s, when they started breeding near fish ponds, which provide food and nesting sites. Fish ponds also enabled the pied kingfisher *Ceryle rudis* to extend its breeding distribution from the Jordan Valley to the coastal plain. Dirt roads surrounding fish ponds and reservoirs are a favorite nesting site of the spur-winged plover *Hoplopterus spinosus*, which has already extended its breeding distribution into the northern Negev. Stilts

Figure 18 The viper *Vipera palaestinae* (reproduced from Tristram (1884) *Fauna and Flora of Palestine*. London: Committee of the Palestine Exploration Fund).

H. himantopus, which once bred only in the Hula swamp area, are now common breeders along the coastal plain on banks of fish ponds and reservoirs. Also, the little-ringed plover *Charadrius dubius* and the Kentish plover *C. alexandrinus*, which formerly bred mainly on the Mediterranean seashore, now breed on reservoir banks. Another wader that breeds on banks, especially of salt ponds in the coastal plain and in fish ponds with brackish water in the Bet Shean valley, is the avocet *Recurvirostra avocetta*.

Among mammals, the coypu *Myocastor coypu* was introduced into the southern Levant for the fur industry during the 1950s. Some individuals escaped from breeding farms, and others were released when their farming was discontinued. Currently, coypu are common near any water body, from northern Israel to the Gaza Strip. The jungle cat *Felis chaus*, which suffered heavily from the draining of wetlands and from poisoning (aimed at jackals and voles) during the 1960s, has fully recovered and occurs mainly near fish ponds. Also, the Egyptian mongoose *Herpestes ichneumon* has expanded, in numbers and distribution, due to the existence of fish ponds. This increase has affected one of its prey species, the water snake *Natrix tessellata*, so that from a very abundant species (traps in fish ponds yielded 30–40 snakes per pond in several days) it has become rather rare. However, the poisoning of jackals also reduced the number of mongooses. This was followed by an increase in the number of snake bites in Israel by the Palestine viper *Vipera palaestinae* (Figure 18) from approximately 200 per year during 1960–1964 to 430 in 1967. Recovery of the mongoose populations was followed by a decrease of snake bite cases to the former level.

In the future, animal diversity in the Levant will be far from the great ecological and zoogeographical variety which makes it so unique.

Glossary

Batha A biblical term for semishrub communities, mainly of seral vegetation of old field succession in the Mediterranean part of the Near East.

Contracted vegetation Vegetation restricted to wadis that receive additional water supply.

Diffused vegetation Vegetation occupying all slopes and most habitats.

Semisteppe batha Semishrub communities developing on most soil types at the boundary of the Mediterranean zone of the Near East.

Wadi Dry water course.

Environmental Conditions

Currently, the most important factors affecting the distribution of species are environmental conditions. The evolutionary history of the area reviewed influenced the composition of the flora, but the environment influences the composition and their ability to coexist and prosper. Before discussing the vegetation and its gradients of species diversity, the physical setup of the study area is discussed.

Topography

The topography of Israel and Jordan can best be described as north–south topographic belts, which are influenced by the geomorphological features of the area. The Mediterranean coastal plain is narrow in the north of Israel (Figure 1, 1) and becomes wide in the south (Figure 1, 5). Low hills with gentle topography and wide valleys with deep soil constitute the foothills. The mountainous area reaches elevations of approximately 1000 m at the Judean Mountains (Figure 1, 12) and the Negev Highlands (Figure 1, 15) and 1200 m at the Galilee (Figure 1, 7). The Jordan–Dead Sea–Arava rift valley is part of the Afro-Syrian Rift Valley and constitutes the lowest topographic element in the area. This valley is 400 m below sea level in the deepest part of the Dead Sea (Figure 1, 24). The terrain ascends to 200 m above sea level (m a.s.l.) at the foot of Mount Hermon (Figure 1, 26) in the north and at the water divide of the Arava Valley (Figure 1, 25) to the south. A few transversal valleys, such as the Esdraelon Plain (Figure 1, 9) running from east to west, dissect the mountainous area into large blocks. Steep escarpments, dissected by canyons, typify the areas east and west of the rift valley. There are a few internal lakes in this valley. Lake Hula between the Golan and Galilee was drained in the 1950s. The Kinneret, also known as the Sea of Galilee, is the largest freshwater natural reservoir of Israel. The Dead Sea is a highly salty water body. The large salt marshes at the Arava Valley are in fact a large underground lake. At the vicinity of these water bodies there are small or large springs. Mount Hermon, at the common border of Israel, Lebanon, and Syria, reaches an elevation of 2800 m and terminates sharply at the basalt-covered plateau of the Golan to the south. This plateau descends gently from an elevation of

1200 m toward the Yarmouch River and toward the Kinneret at 200 m below sea level. The Jordanian plateau starts south of the Yarmouch River (Figure 1, 28). Its escarpments delimiting the rift valley are as steep as, and in many places steeper than, the escarpments in Israel. The Jordanian plateau has several peaks 1200–1600 m high. A few deep rivers dissect the plateau from east to west toward the rift valley. East of the water divide, which is near the western edge of the plateau, the landscape becomes flat and gradually descends toward Mesopotamia.

Sinai has a wide coastal area along the Mediterranean Sea (Figure 1, 32), ascending gradually southward. The northern Sinai sand belt reaches the anticlinal ridges of Gebel Maghara, Gebel Halal, and Gebel Yiallaq (Figure 1, 33). The central Sinai gravel plains (Figure 1, 35) are surrounded by crescent-like ranges of mountains or plateaus (Figure 1, 36), dissected by a few valley passages such as those of Wadi Giddi, Wadi Mitlah, and Wadi Sidr. South of the gravelly plains there are two large plateaus ascending gradually in a north–south direction. The Gebel el Igma plateau (Figure 1, 37) peaks at 1600 m and the Gebel et Tih plateau peaks at 1400 m. The erosion escarpments of the two plateaus are steep and that of the latter descends to the sandstone belt. The morphology of the sandstone belt (Figure 1, 41) is highly diverse in different parts of Sinai. The Southern Sinai Massif (Figure 1, 42 and 43), built of magmatic and metamorphic rocks, is highly dissected topographically. The mountain peaks reach 2500–2600 m. The escarpments toward the Gulf of Elat-Aqaba are not as steep as those of the rift valley in Israel and Jordan. The coastal plain along this gulf is wide in the southern part of Sinai, whereas in many places the mountain slopes descend directly into the sea without any coastal plain. There is a wide coastal plain along the Gulf of Suez.

Rock Types, Geomorphology, and Edaphic Conditions

The most common rock types of northern Israel and Jordan are sedimentary limestones, dolomites, chalks, and marls of the Cretaceous and the Tertiary. Terra Rossa soils occur in the mountainous areas on hard rocks, and Rendzinas occur on the soft ones. Basalt rocks typify much of the Golan plateau and northeast Galilee. Both are covered with basaltic brown or red Mediterranean soils. Tertiary and Pleistocene rocks and

derived soils fill up the small and large valleys. Calcareous sandstone, locally known as kurkar, and sandy-loamy soils, known as hamra, typify the coastal plain near the coast and deep clay soils, known as grumusols or vertisols, far from the Mediterranean coast. Cretaceous and older sandstone typify the vicinity of the rift valley of the Jordan River, the Dead Sea, and Arava in Jordan. The edaphic conditions in northern Jordan and south to Amman are similar to those of the area west of the Jordan River.

The steppe and desert areas of Israel, Jordan, and Sinai develop on a much more diverse assemblage of rocks. The main contributors are limestone, chalk, marl, chert, sandstone, magmatic, metamorphic rocks, and gravel of alluvial origin or rocks weathered *in situ*. Loess is important eolian sediment, composed mainly of silt and clay particles, that much influences the soils of the transition zone of the Mediterranean territory and the steppelands. Large flatlands south of this transition zone occur in the northern Negev of Israel and east of Irbid, Jarash, and Amman in Jordan. The poor moisture regime of loessial soils with low quantities of rainfall makes the desert boundary prominent.

Dan *et al.* (1975) provide soil maps of Israel, and Al-Eisawi (1996) provides a map of Jordan; a detailed soil map of Sinai is not available. The specific influence of each substratum type on the vegetation is discussed in detail elsewhere (Danin, 1983). The relationships between rock type, soil, and vegetation in the desert areas of Israel and Sinai are similar to those in many areas of Jordan.

Geomorphological structures in Israel are small, and they are larger in Sinai and Jordan; however, these are smaller than those in countries such as Saudi Arabia in which huge areas of similar structures occur. This is the expression of relatively high geomorphological diversity. One might expect to find a high diversity of rock and soil types under a certain climatic regime. Hence, habitat diversity in such areas is expected to be high.

Climate

Rainfall

The climate of Israel, Jordan, and Sinai is Mediterranean, characterized by a cold and rainy winter and a rainless and warm summer. Rainfall quantities vary in two directions: rainfall decreases gradually from north to south – sharply from the water divide eastward in Israel and gradually in Jordan from the water divide eastward (Figure 2). The north–south gradient is influenced mainly by the intensity and frequency of rain-contributing systems, whereas the west–east gradients are influenced by the topography. Thus, the ascent of air bodies from the Mediterranean Sea toward the mountains of Judea, Samaria, and Galilee results in cooling of the air and an increase in rainfall with increasing elevation. Air bodies descending toward the rift valley become warmer and drier; hence, the Samarian and Judean Deserts and the eastern Galilee occur at the rain shadow of the Judean, Samarian, and Galilee mountains, respectively. The ascent to the Jordanian plateau mirrors the rainfall map with maximum at the mountaintops. There is a gradual decrease in mean annual rainfall eastward with increasing continentality far from the Mediterranean toward the desert. The increase in mean annual rainfall in Moav and Edom, located south of the west–east section of the 300-mm isohyet in Israel, is related to the orographic influence of the high elevation of this area. Snow may fall in winters of cold and wet years on the highest summits of mountains in Israel, Jordan, and Sinai and remain for a few days.

Dew and Fog

Dew and fog are important sources of humidity for the poikilohydric organisms growing on rock outcrops. The measurement of dew by Duvdevani's dew gage indicated a high

Figure 2 Mean annual rainfall map.

similarity to events of efficient dew when lichens imbibed on stones and rocks at the Negev Highlands. The mean annual number of nights with more than 0.02 mm per night of dew has been 191 ± 22 for the past 15 years at Avdat; of these, there are only 124 ± 28 nights annually with dew amounts of 0.11–0.5 mm. Dew measurements in other parts of Israel, Jordan, and Sinai are not available. However, lithobiont communities near Avdat were used to extrapolate the regional distribution of dew. There are many similarities in weathering features found at the top of the northern Sinai anticlines (Figure 1, 33) and on limestone outcrops at the area marked 11d in Jordan (Figure 3). The author assumes that the dew and fog regime is similar in the latter two areas to that of the Avdat area where real measurements of dew and rainfall were carried out.

Temperature

Temperature regime in the study area is influenced by the altitudinal and latitudinal position of the site under review. Mean annual temperature in the desert areas varies from 9 to 25 °C. The lowest temperatures prevail in the peaks of southern Sinai and Jordan near Shoubak, whereas the highest are those of the Dead Sea and Arava Valleys, where elevation

reaches 400 m below sea level. Mean annual temperature maps of Israel are presented in the atlas of Israel and of Jordan in Al-Eisawi (1996).

Flora

There are 2682 plant species in Israel, including approximately 200 species which occur in the Mt. Hermon area and are absent in the other districts of Israel. The number of species in Jordan is 2078, according to Al-Eisawi (1996). There are 2885 species in the combined lists of plants of Israel and Jordan

(A. Danin, unpublished data). The vast species richness of Israel, expressed as the parameter of species to area (Table 1), is related mainly to the following factors:

1. Its position in a meeting zone between plant geographical regions, each with its own typical flora.
2. The existence of many habitats needed to support these species: The wealth of habitats derives from the climatic transition between the relatively moist area in the northern part of the two countries and the extreme desert areas in their southern part and also in Jordan's eastern part. Topography is also a factor in creating the warm climates of the rift valleys and the relatively cold climate of the mountainous areas. Similarly, other highlands and lowlands have local climatic influence, which increases the habitat diversity of Israel and Jordan and increases the number of habitats which support much plant species diversity. The large number of rock types influences the development of many soil types in a small area, increasing the diversity of habitats available for plants.
3. A long history of human pressure of cultivation and grazing by domestic animals led to a strong stress on the existing flora and enabled the introduction of many alien species, many of which occupy habitats created by human activity.

According to the various studies of the flora of Israel, it may be divided into the following groups:

1. Mediterranean species, which are distributed around the Mediterranean Sea.
2. Irano-Turanian species, which also inhabit Asian steppes of the Syrian desert, Iran, Anatolia in Turkey, and the Gobi desert.
3. Saharo-Arabian species, which also grow in the Sahara, Sinai, and Arabian deserts.
4. Sudano-Zambesian species, typical of the subtropical savannas of Africa.
5. Euro-Siberian species, also known in countries with a wetter and cooler climate than that of Israel. These species grow mainly in wet habitats and along the Mediterranean coasts.

Table 1 Species richness of the flora of several countries

Country/State	Species	Area (km ²)	Species per 100 km ²
Israel	2682	29,600	9.06
Sinai	889	61,100	1.45
Egypt (excluding Sinai)	2100	1,000,000	0.21
Saudi Arabia	2200	2,200,000	0.1
Syria	3060	185,000	1.65
Spain	5500	504,000	1.09
Tunisia	2250	164,000	1.37
Greece	4200	132,562	3.17
Italy	5600	301,100	1.86
Britain	1666	229,850	0.72
California	5057	411,000	1.23

6. Biregional, triregional, and multiregional species that grow in more than one of the regions mentioned previously.
7. Alien species derived from remote countries; these plants propagate without human assistance.

Vegetation

Danin (1999) discusses the vegetation of the entire area in detail. The most prominent factors influencing the vast species diversity of the study area are discussed in the following sections. The reader may combine the general information on the vegetation of Israel (Danin, 1999) with that of Sinai (Danin, 1983) and Jordan (Al-Eisawi, 1996).

Maquis and Forests

The principal spontaneous woodland areas of Israel are found in the mountains of Judea, Carmel, and Galilee and at the foot of Mt. Hermon; those of Jordan occur north of Amman (Figure 3, 1). These forests or maquis are dominated by the sclerophyllous evergreen *Quercus calliprinos* and the deciduous *Pistacia palaestina* and grow on hard limestone with terra rossa soil. The companions of *Q. calliprinos* vary according to edaphic and climatic conditions. In the mesophytic aspect of the oak woodlands, found mainly in Upper Galilee, there are several trees, shrubs, vines, and geophytes that are not found in the xerophytic aspect of the southern Judean Mountains. In the driest maquis stands, *Rhamnus lycioides* subsp. *graecus* is the only arboreal companion of *Q. calliprinos*. Typical vines in these maquis are *Rubia tenuifolia*, *Lonicera etrusca*, *Asparagus aphyllus*, and *Ephedra foeminea*.

Marly chalk is a common rock type that has high moisture-holding capacity and is covered with a shallow light rendzina soil. The aeration of the rhizosphere, of trees and shrubs that penetrate into the soft rock, is poor and leads to nutritional stresses, which only specially adapted plants can withstand. Much of the nitrogen in these soils is in the form of ammonium ions, whereas in the terra rossa it is in the nitrate ion form. The vegetation cover of the light rendzinas on marly chalk is found poor when compared with that on terra rossa and includes very few annual species. The principal trees of these soils are *Arbutus andrachne* and *Pinus halepensis*.

In most of the area, cultivated plants have replaced the spontaneous trees. A few thousand years ago, people in the eastern Mediterranean countries started to clear the natural vegetation to create agricultural land. Trees such as olives (*Olea europaea*) and almonds (*Amygdalus communis*), which grow spontaneously in the area, have been domesticated. Timber derived from the forests and maquis was used for the construction of houses, for agricultural tools, and for fire fuel. For the past few millennia shepherds have burned large woodland areas to open paths for domestic animals, and the pasture quality has been improved through the replacement of trees and shrubs with palatable herbaceous plants.

As a result of thousands of years of deforestation and agricultural and urban development, large areas of Israel and Jordan look like mosaics of seral communities. Abandoned

cultivated ground becomes populated for dozens of years by herbaceous and low lignified plants. Habitat diversity, and thus species diversity, is extremely high due to the removal of the shading trees and the opening of poor and temporary fertile soils to annual plants which could not grow in the closed woodlands. Frequent human-induced fires reopen areas, which become populated with shading trees and shrubs and ephemeral plants that increase species diversity. Some terra rossa soils, which are leached and poor, become fertilized during the years of crop cultivation. Once abandoned, a series of replacement annual plant communities occurs, from those using fertile ground, including tall plants, to those using poor soil and being small in size. By sampling approximately five such stages, each a square of $1 \times 1 \text{ m}^2$, in the vicinity of Jerusalem, the author found approximately 100 different species in 8 m^2 . Local enrichment of the poor soils by gazelle droppings and at the vicinity of nests of harvesting ants creates an ecotone of soil fertility, which enables the coexistence of many species.

Light rendzinas were often cultivated due to the high water-holding capacity of the substratum of soil plus rock. When abandoned, this soil may support the growth of a few annual species. After time passes and the aerated plowed soil becomes flattened, microbiotic crust, including cyanobacteria, lichens, and mosses, develops on the surface, thus influencing soil aeration and changing edaphic conditions. Such minute edaphic changes along the precipitation gradients of the mountainous areas (Figure 2) contribute to the vast species diversity of the country.

Q. calliprinos Woodlands on Basalt

The basalt flows of the northern Golan are younger and differ in rock types from those of the rest of the Golan. The vegetation constituting these woodlands (Figure 3, 2) is rich in herbaceous companions. In contrary to the vegetation of the calcareous rocks, they are almost devoid of semishrub communities at the early succession stages because of destruction and abandonment. The main environmental factor influencing this is the high phosphorous content of the rock and soil, which favors the development of ephemeral plants. Thus, a dense maquis of *Q. calliprinos* covers the gentle north-facing slope of the ancient volcanic cone of Har Odem, the Golan, at an elevation of 900–1000 m. Regarding the trees, the rich ephemeral vegetation includes approximately 20 species of Trifolium, many other Papilionaceae, and rich annual flora of other families. The phytomass is low, thus indicating some nutrient deficiency when compared to that of the vegetation of other basalt flows. Under such conditions, without one dominant species there is high species diversity.

Other basalt rocks derived from older basalt flows at lower elevation, down to 500 m a.s.l., support denser and taller ephemeral vegetation with different composition due to differences in soil fertility and climatic conditions, which follow elevation. The oak trees and their arboreal companions are found only occasionally and they have no impact as shadow creators in most of the Golan and eastern Galilee.

Ancient volcanoes provided much volcanic ash to large areas surrounding them. Because of a different phylogenetic

nature, this substratum supports a rich flora, many components of which are not common in other kinds of soil in this area. Many of the volcanic ash layers have a porous and well-aerated texture. In contrast to the grumusols and proto-grumusols of much of the area surrounding it, this substratum supports many narrow-range species.

Montane Forest of Mt. Hermon

The montane forest (Figure 3, 3) stretches at Mt. Hermon from 1300 to 1700 m a.s.l., where there are only scattered remnants of the woodlands which are believed to have been there before their destruction by human activity. The dominants are deciduous trees such as *Quercus boissieri* and *Quercus libani* and several species of *Crataegus*, *Amygdalus*, *Acer*, and *Prunus*. Their companions are mainly perennial grasses and many herbaceous species that differ from those of the rest of the Mediterranean territories of the Near East. These occur at lower elevation and presumably thrive on a different temperature and rainfall regime than that of the montane forest. There are no representative areas of this category in Jordan because there are no mountains of this elevation in the northern part of the country. However, in southern Jordan, there are such high mountains, but due to their drier climate woodlands of this kind are absent. Nonetheless, a few representative shrubs of the genera *Astragalus* and *Cotoneaster*, common at Mt. Hermon, occur at high elevations in crevices of smooth-faced rocks in southern Sinai and in southwestern Jordan.

Open Forests of *Quercus ithaburensis*

The tabor oak is the most frequent tree in the open forests prevailing in large areas of Israel and Jordan (Figure 3, 4). *Syrax officinalis* also appears with the tabor oak when developed on chalky ground of the Lower Galilee, Israel, and the Gilead in Jordan. *Pistacia atlantica* is the companion on basalt rocks of the Golan. Plenty of herbaceous plants cover the open space among the trees in all areas of this category. The few semishrubs found in this community when developing on chalky ground are mainly of *Majorana syriaca*. This is contrary to the dominance of *Sarcopoterium spinosum*, the typical component of seral communities on terra rossa. This type of forest, which once dominated the Sharon Plain, is restricted in the Sharon (Figure 3, 4) to solitary, sporadic tabor oak trees that survived urbanization and agricultural development. There are large woodlands of the tabor oak in the Lower Galilee and in the Golan, lower than 500 m. Some of the largest indigenous trees in Israel are those of tabor oak at the Hula and Dan Valleys in the northern section of the rift valley in Israel. The tabor oak woodlands of the northwest of Jordan are well preserved. They cover large areas of rocky terrain west of Irbid, at the western escarpments of the Jordanian plateau, from sea level to 500 m a.s.l. The drier and more continental climate of the Jordanian woodlands allows for a different assemblage of companions to the oak.

Open Forests of *C. siliqua* and *Pistacia lentiscus*

Open woodlands dominated by carob trees and shrubs of *P. lentiscus* cover the lower altitudinal belt of the main

mountain ranges, 0–300 m on both sides of the central mountain range on terra rossa soils. This community inhabits rendzina soils at the foothills of the Judean mountains and sandy soils of the Sharon Plain in the littoral aspect of the community (Figure 3, 5). Generally, the community is more drought and heat resistant than the communities dominated by *Q. calliprinos* and has a similar position in the aridity sequence of communities as those dominated by the tabor oak. Wild olive (*O. europaea* var. *sylvestris*), which resembles the cultivated olive but has much smaller fruits, is an important companion of the carob in rocky sites at Mt. Carmel and Galilee. In Jordan, this category is almost missing; however, scattered carob trees occur in the open woodlands of *Q. ithaburensis* of the Gilead, mainly in the transition zone from the belt dominated by the tabor oak to that of *Q. calliprinos* at elevations of 500–600 m. The main companion of the carob at the southern Judean foothills is *R. lycioides* subsp. *graecus*. The latter totally replaces all the other arboreal components in dry habitats.

The flora of this community is rich due to high habitat and microhabitat diversity. The hard limestone rocks have many crevices and soil pockets, which enable diverse microhabitats supporting different species to coexist that are isolated from each other by the rock body. Soft chalk rocks, covered by hard nari crust, also known as caliche, constitute additional diverse habitats. The nari layers have an upper hard crust layer of 5–10 mm, which covers softer rock but is still consolidated chalk. Trees and shrubs, the roots of which penetrate into the rock, may establish themselves, thus avoiding the competition of the rich herbaceous flora which accompany them in the deep soil pockets. Thus, in many places the local boundary of the land dominated by shrubs and trees coincides with that of the nari rocks. Various kinds of shade are provided by evergreen trees and shrubs, each having a different architecture that influences the companion life. Opened for grazing by domestic and wild animals, the potential strong competition ordained by a few herbaceous plants is decreased, thus enabling many species to coexist.

Ziziphus lotus with Herbaceous Vegetation

The phosphorus-rich soils developing on basalt rocks of southeastern Galilee and the slopes of the Golan near the Sea of Galilee and limestone and other sedimentary rocks down to the Samarian desert support grasslands dominated by Gramineae with large seeds. The most common grasses are wild wheat (*Triticum dicoccoides*), wild barley (*Hordeum spontaneum*), and wild oats (*Avena sterilis*). This area (Figure 3, 6) contains the highest genetic diversity of these species, which are believed to have been domesticated in the Near East thousands of years ago (Zohary and Hopf, 1993). A similar formation covers the west-facing slopes of the Gilead, Jordan, below the tabor oak belt. In drier and warmer sites or sites at which the soil is shallow, *Stipa capensis* is the dominant plant. The lignified and thorny shrub *Z. lotus*, spread as green patches over the area, typifies most areas of these grasslands. Sites of relatively high soil fertility, common in this plant community, are the nests of the harvesting ant *Messor messor* and piles of dung of the male gazelles (*Gazella gazella*). This category is presented as a mosaic

with that of the savannoid Mediterranean vegetation (Figure 3, 7) in the steep topography at the vicinity of the rift valley north of Jericho to north of the Sea of Galilee.

Mediterranean Savannoid Vegetation

Warm, stony/rocky slopes of the Galilee, Golan, Gilead, and Samaria descending to the rift valley (Figure 3, 7) at sea level and below are covered with grasslands of Mediterranean annuals with large seeds, such as wild wheat, barley, and oats, and scattered *Ziziphus spina-christi* trees. The latter is a low, thorny tree with edible fruits that also grows in true savannas in Africa, where its companions are Sudanian perennial grasses. Therefore, the vegetation here is named “savannoid.” Stands of this tree are also established along the transversal valleys on deep clay soils and along the Sharon Plain, where it grows on sandy-loamy soils together with the grass *Desmostachya bipinnata*. Local diversity of nutrients and derivative high species diversity are caused by harvesting ants and gazelles as discussed previously (see Maquis and Forests).

At the Bet-Shean Valley south of the Sea of Galilee there are considerable areas of slightly saline springs, the salts of which remain in the soil while water evaporation occurs. This results in a wide range of microhabitats, which vary in soil salinity and the availability of spring water. The northernmost site of *Balanites aegyptiaca*, an African savannah tree, is in the vicinity of one of these springs. The Sudanian mistletoe *Plicosepalus acaciae* (= *Loranthus acaciae*) has its northernmost site on these *Balanites* trees.

Semisteppe Batha

Semishrub communities of the *Ballotetea undulatae* at the boundary of the Mediterranean zone (Figure 3, 8), where mean annual rainfall is 300–400 mm, are regarded as semisteppe bathas. There are several communities dominated by Mediterranean plants such as *S. spinosum*, which dominates bathas in more mesic parts of the country. Others, such as *Artemisia sieberi* and *Noaea mucronata*, dominate steppe areas in the Negev, Sinai, Jordan, and eastward to Afghanistan. Many plants that play an important role in the seral communities in fallow fields at the center of the Mediterranean region grow here in what is regarded as their primary habitats. No anthropogenic disturbance assists or enables their growth here, and they occupy their typical habitats that are related to certain edaphic and climatic conditions. *S. spinosum*, which becomes ethiolant and dies under the shade of trees and shrubs in the course of plant succession in maquis and forests, has no such competitors in the semisteppe bathas. The semisteppe bathas extend further south and east of the regional boundary of the maquis in Jordan and in Israel. Because semishrubs are the dominant tallest growth form, the semisteppe bathas are rich in their flora. Many plants of mesic and xeric origin coexist here, contributing to the vast species diversity. Phytogeographical analysis of each association in this vegetation indicates a higher diversity in origin when compared to the associations of drier and moister conditions.

Tragacanth Vegetation of Mt. Hermon

Semishrubs that look like thorny cushions constitute the most prominent formation of vegetation developed on the windward slopes of the peaks of Mt. Hermon above 1900 m (Figure 3, 9). Many species of section *Tragacantha* in the genus *Astragalus* and of the genus *Acantholimon* are components of the cushion plants formation throughout the Middle East. The thorny cushion seems to have some biological advantages, which make it adaptable to some of the components of the harsh conditions of this habitat: cold winter with high-velocity winds, precipitation mainly as snow, and dry summer. The short growth season and the harsh environment are the main factors enabling the success of very few annual species as companions of the cushion plants.

Snow accumulates on the slopes in the wind shadow of small local ridges or crests because of the low wind velocity. Consequently, snow may reach a depth of 10 m for a few months. Water drainage from the slopes of this area is through karst systems and not through wadis as in many areas of the country. A common feature of the karst topography is the occurrence of small valleys, which are filled with fine-grained soil known as dolinas. The soil in these valleys is waterlogged for a long time, thus increasing habitat diversity and the growth of many additional species compared to those of the rest of Israel.

Several species of tragacanth *Astragalus* occur in areas which are far from Mt. Hermon and the Anti Lebanon mountains. *Astragalus bethlehemiticus* is a typical companion of steppes and rock vegetation in the shrub-steppes and semi-steppe bathas of the Negev Highlands and of southwestern Jordan; *Astragalus echinus* is a representative of this group at the high elevations of southern Sinai, where it is confined to crevices of smooth-faced granite.

Vegetation Patterns in the Dry Areas of Israel, Jordan, and Sinai

When dealing with the vegetation of drylands, which receive less than 200 mm mean annual rainfall, one has to consider general patterns of distribution of vegetation. The two principal patterns of distribution of vegetation in the dry areas of the Near East are related to dry watercourses, which are known as wadis from the Arabic language or arroyos in the southwestern US. Wherever plants grow on slopes and depressions, the pattern is regarded as "diffused." In extremely dry desert areas, where vegetation is restricted to wadis that receive additional water supply, the pattern is "contracted." In an area in which the climatic conditions enable the development of diffused vegetation on most soil types, silty or clayish soils, which are relatively dry soils in desert will locally support contracted vegetation. Plants demanding relatively high quantities of moisture may inhabit special habitats of wadis in zones of contracted vegetation. Such special habitats are derived from local contribution of runoff water from rocks to their crevices and soil pockets. In hard and fissured limestone, dolomite, granite, and metamorphic rocks, much of the rainfall is available to the semishrubs growing there because water infiltration is good and the soil in the rock fissures is leached. Accumulating deep in the soil and the weathered rock, this water is protected from direct evaporation by rocks and stones.

Trees that grow on slopes of the Mediterranean zone that receives 500–700 mm of annual rainfall occur in desert areas with 100 mm or even less in proximity to outcrops of smooth-faced hard rocks. These rocks do not absorb much water and their crevices receive high amounts of water through runoff (Danin, 1999).

One of the ways in which plants are adapted to desert conditions is that they avoid the extremely dry season, which may last from 6 months to several years. Thus, annual plants may be seen in some habitats every few years. This depends on edaphic and climatic conditions; for example, annual halophytes may germinate and grow to produce seeds only on salty soils and only in rainy years when the soil solution is diluted to the appropriate level. However, annuals that develop in crevices of smooth-faced rocks may have sufficient resources to be sustained almost every year. Thus, species diversity in the desert may be high in areas in which habitat diversity is high, especially if there are sufficiently large outcrops of smooth-faced hard rocks, which contain many different microhabitats.

Shrub-Steppes

The area of the Negev Highlands, the Judean Desert, Sinai, and southwestern Jordan, which receives 80–250 mm of rainfall annually, is covered with semishrubs at a diffused pattern, thus forming shrub-steppes (Figure 3, 10). The most common dominants in these steppes are *A. sieberi*, *Noaea mucronata*, and *Gymnocarpus decander*. The phytomass produced by annuals in the plant communities developing on stony or rocky shallow soils is always small when compared with that of fine-grained and deep soils. The latter types hold much of their water close to the soil surface, thus losing much of it through direct evaporation. The minute quantities of 8 ppm of salts carried by clouds and later by rain from the Mediterranean Sea by climate systems remain in the soil and accumulate there. The soil may be too dry or too saline for the growth of annuals in regular or dry years. Nearly monospecific communities of semishrubs exist, each best adapted to the specific local saline conditions. The most common dominants under these conditions are *Reaumuria hirtella*, *Reaumuria negevensis*, *Salsola vermiculata*, *Bassia (Chenolea) arabica*, and *Atriplex glauca* on chalk- and marl-derived soils; *Anabasis syriaca* and *Haloxylon scoparium* are the shrubby dominants on loess-derived soils. However, in moist years there is much development of annuals, although in patches with high salinity there are monospecific patches of salt-resistant annuals. Showy geophytes such as species of *Tulipa*, *Iris*, *Ixiolirion*, *Ranunculus*, and *Anemone* may bloom in large quantities in the shrub-steppes in moist years.

Outcrops of smooth-faced hard limestone support plants that differ much from those on the other soil types. This vegetation is typically characterized by *Chiliadenus iphionoides*, *C. montanus*, *Globularia arabica*, *Stachys aegyptiaca*, *Polygala negevensis*, *Tanacetum sinaicum*, and *Capparis aegyptia*. Isolated populations of dozens of Mediterranean relicts and many rare desert plants are found in this habitat in the Negev, the Judean Desert, Sinai, and Jordan. The semishrub *S. spinosum* and the geophytes *Narcissus tazetta* and *Sternbergia clusiana* are examples of this phenomenon in the Negev (Danin, 1983).

Several species that were discovered as endemic and new to science and many species that were not previously collected in the steppe areas of the Near East are confined to this habitat (Danin, 1999, 2008; Danin and Künne, 1996).

Shrubs of *Retama raetam* and *Achillea fragrantissima* are the dominants in wadis of the terrain of hard limestones. *Atriplex halimus* prevails in this habitat, in which the catchment area is built up from the salty soils on chalk, clay, or marl. At lower elevations, *Acacia raddiana*, *Acacia pachyceras*, *Tamarix nilotica*, and *Tamarix aphylla* also occur. Many small springs exist in the limestone hills of western Sinai and the sandstone hills of southwestern Jordan. Most of these springs can be detected from afar by the date palm (*Phoenix dactylifera*), which is confined to sites with a high water table of freshwater. It is accompanied by *Nitraria retusa*, *Juncus arabicus*, *Phragmites australis*, and *Cressa cretica*. Canyons occur in many wadis and may have long-lasting water pools supplied by floods and support rich flora of hydrophytes such as *Zannichellia palustris* and *Potamogeton* spp. and green algae such as *Chara* spp.

Shrub-Steppes with Trees

Shrub-steppes similar to those discussed previously (see Shrub-Steppes) cover most of the area of this category (Figure 3, 11); however, prominent trees occur in special habitats sporadically. Approximately 1400 adult trees, most of which are *P. atlantica*, accompanied by a few *Amygdalus ramonensis* and *Rhamnus disperma* trees and shrubs (Danin, 1983), typify subunit 11a in the Negev Highlands and eastern Sinai. The trees are found in affinity to outcrops of smooth-faced rocks. The high yields of runoff water from the rocky outcrops to their crevices enable the successful germination and establishment of seedlings even outside of wadis. Sufficiently large outcrops of limestone support trees, some of which are several hundred years old. Wadis with such outcrops in their catchment area support large trees. Rare relicts, such as the vines of the Mediterranean maquis *Prasium majus* and *E. foeminea*, and endemic plants such as *Origanum ramonense*, *Bufonia ramonensis*, and *Ferula negevensis* also occur in these rocks.

Juniperus phoenicea is the tree of subunit 11b. Of the three anticlinal ridges of northern Sinai, Gebel Halal is the richest in trees and accompanying rare plants. The junipers occur in crevices of smooth-faced limestone outcrops and in wadis. Rare Mediterranean relicts which occur in the rock crevices are *E. foeminea*, *R. tenuifolia*, and *Astomaea seselifolium*. A rare component of the rock vegetation is *Origanum isthmicum*, which is endemic to a small area in Gebel Halal ridge. Its closest relative, *Origanum jordanicum*, was discovered in Jordan near Petra (Danin and Künne, 1996). The juniper populations of Gebel Maghara and Gebel Yiallaq grow mainly in wadis.

Subunit 11c is richer both in nondesert trees and shrubs and in companions. The large outcrops of smooth granite and the high elevation of southern Sinai Massif result in a high number of habitats available for the survival of rare species. The typical trees of the rocky environment in 11c are *Pistacia khinjuk*, *Crataegus sinaicus*, and *Ficus (pseudosycamoros) palmata*. The west-facing escarpments of Gebel Serbal are rich in *Moringa peregrina*, which also grows in the vicinity of Wadi Feiran oasis. The typical shrubs of the rocky habitat of 11c are *R. disperma*, *Rhus tripartita*, *Cotoneaster orbicularis*, *Periploca aphylla*, and *Sageretia thea*.

Most of the endemic and rare species of Sinai occur in the crevices of rocks that also support trees.

The *Q. calliprinos* and *J. phoenicea* woodlands in Edom, Jordan, are marked 11d on the vegetation map. The climatically controlled belt of the arboreal Mediterranean vegetation terminates in the vicinity of Amman, approximately 120 km north of the Dana-Tafila area. Large areas of shrub-steppe, semisteppe batha, and steppe-forest typify the western ridge of the Jordanian plateau between At-Tafila and Petra. These are dominated by *A. sieberi*, *N. mucronata*, *Argyrobolium crotalaroides*, and thorny species of *Astragalus*. The occasional arboreal components include *P. atlantica*, *Crataegus aronia*, *J. phoenicea*, and *Q. calliprinos*. These formations develop on fissured limestone, basalt, and chalk rocks. The smooth-faced hard sandstone outcrops of the Dana-Petra area support the richest relict Mediterranean flora in the Near East. The trees and shrubs growing here are *Q. calliprinos*, *P. atlantica*, *P. palaestina*, *P. khinjuk*, *C. aronia*, *J. phoenicea*, *Amygdalus korschinskii*, *Ceratonia siliqua*, *O. europaea*, *A. andrachne*, *Rhamnus punctata*, *R. lycioides*, *R. disperma*, *Ficus carica*, *F. palmata*, and *Sageretia thea*. Typical root parasites of the Mediterranean maquis, such as *Osyris alba* and *Thesium bergeri*, occur in the rock crevices, as do typical vines of the maquis – *R. tenuifolia*, *E. foeminea*, *Hedera helix*, *Bryonia cretica*, and *L. etrusca*, which are represented by a higher number of individuals than other Mediterranean vines in any other refugia in the Near East. The rich Mediterranean flora with many endemics may be regarded as existing in a successful refugium, which has functioned for a long time in the evolutionary history of the region. Of the many endemic species of unit 11d species discovered recently are *Origanum petraeum*, *O. punonense*, *O. jordanicum*, *Pycnocycla saxatilis*, *Rubia danaensis*, *Micromeria danaensis*, and *Silene danaensis*.

Desert Vegetation

Sparsely vegetated shrub-steppes dominated by *Anabasis articulata* and *Zygophyllum dumosum* occur at the broad boundary area of the desert with the steppes zone (Figure 3, 12 and 10). These typical semishrubs of the desert grow in this transition zone in a diffused pattern. Chalk and marl outcrops are populated with the xerohalophyte communities of *Suaeda asphaltica*, *Salsola tetrandra*, *B. (Chenolea) arabica*, and *Haloxylon negevensis*. The nearly monospecific communities of semishrub xerohalophytes are accompanied by a diverse assemblage of herbaceous plants that grow on the leached soil only in rainy years.

The extreme desert areas may have no higher plants growing out of wadis, but the entire area may be covered by a highly diverse microbiotic crust. Dor and Danin (1996) studied the microbiotic succession and changes in floristic composition of the crust in the Dead Sea area.

The sequence of plant communities along the wadis of a more arid zone of this category is typified by a stretch of annuals which occur in rainy years. The nature of the annuals community is heavily influenced by the edaphic and climatic conditions of the site. A lower section of the wadi receives higher quantities of water and supports small and short-living semishrubs such as *Pulicaria incisa*, which may function locally as an annual. Further down, larger and long-living semishrubs

such as *A. articulata* or *Z. dumosum* grow. A section dominated by shrubs such as *R. raetam*, *Ochradenus baccatus*, or *Lycium shawii* prevails further down the wadi system. In the lowest section of the wadi system, trees, mostly *Acacia* species or *Tamarix* species, may be found. The nature of plant communities and the sequence of their occurrence along the wadis are in close affinity to rock and soil types, which greatly influence the moisture, salinity, and nutrient regime in the wadi systems.

In similar gravel plains in the large desert area south of Ma'an to the Saudi Arabian border, *A. articulata* grows with trees of *A. pachyceras* at the fifth-order section of the wadi system. The rocky terrain at the escarpments of southwestern Jordan to the Arava rift valley supports diverse communities in a diffused pattern as occurs in Sinai and the Negev.

Sand Vegetation

The main areas in which sand dunes or sand sheets occur in Israel (Figure 3, 13) are the Mediterranean coastal plain, the western Negev, a few valleys of the northeastern Negev, and the Arava Valley. Different climatic regimes prevail in each of these areas, sand texture differs, and hence the vegetation and processes of its development differ accordingly. Much of this vegetation, patterns of species diversity, and the nature of the microbiotic crust of the sand in desert areas are discussed in other publications. Thus, some background concerning the sand vegetation of southern Jordan is presented here.

Weathering of Nubian sandstones in the Jordanian plateau contributes mobile sand to the Arava Valley. The relatively high water table at the Arava enables the successful development of the tall shrub *Haloxylon persicum* at sites in which sand is sufficiently deep. However, most stands of this plant in Israel became intensively irrigated agricultural areas. Nonetheless, large areas of *Haloxylonetum persici* cover considerable areas of the Arava, southeastern Sinai, and the southeastern desert of Jordan (Al-Eisawi, 1996). Annuals accompany the shrubs of the sand sheets in rainy years. The sandstone area of the Jordanian plateau is built of sandstone inslebergs, which project from large flat valleys and are filled with stable sand. Huge areas of sand sheets in the Wadi Rum area are dominated by *H. salicornicum*, *A. articulata*, and occasional patches of *H. persicum*. The sandstone hills support many relict Mediterranean species and there is particularly interesting vegetation at the vicinity of the contact zone between the sandstone and the Precambrian crystalline rocks.

Oases with Sudanian Trees

The climate of the rift valley is much warmer than that of the hilly terrain surrounding it. Springs in which a high quantity of freshwater is available throughout the year (Figure 3, 14) support thermophilous Sudanian trees such as date palms (*P. dactylifera*), *A. raddiana*, *Acacia tortilis*, *Calotropis procera*, *Moringa peregrina*, *B. aegyptiaca*, *Cordia sinensis*, *Maerua crassifolia*, *Dalbergia sisoo*, *Capparis decidua* (in Jordan), and *Z. spinachristi*. Rich annual flora may accompany sites that are not under the influence of the spring water but successfully grow in rock crevices, soil patches, and abandoned cultivated land.

In many freshwater springs/oases near the Dead Sea in Israel and Jordan and in southern Sinai, *Adiantum capillus-veneris* grows on dripping water at shady places with the orchid *Epipactis veratrifolia*. A prominent species of the freshwater springs in the Jordanian desert, *Nerium oleander*, is absent from the desert springs of Israel and Sinai.

Desert Savannoid Vegetation

A considerable part of the Arava and Dead Sea Valleys is covered by savannoid vegetation in which *Acacia* trees are accompanied by desert semishrubs (Figure 3, 15). In wadis, the upper soil layers support the typical desert vegetation. *Acacia pachyceras* is the dominant tree of areas that are at a relatively high elevation, such as the upper tributaries of Nahal Paran in Israel, Wadi Jirafi in Sinai, and large areas of gravel plains in Jordan south of Ma'an. *Acacia raddiana*, which is less resistant to low temperatures, is the dominant tree at lower elevations, and *A. tortilis*, which has the highest demands for high temperatures, grows in the southern Arava or below sea level in the northern Arava and Dead Sea Valley. In a few places between Wadi Watir and Sharm el Sheikh in eastern Sinai, rare trees of *C. decidua* grow, which is an important component of the savannah vegetation of southern Egypt and Sudan.

Swamps and Reed Thickets

Only small nature reserves, such as that of the Hula Lake, remain (Figure 3, 16) from the swamps that covered large areas at the beginning of the twentieth century. Freshwater springs still flow and their vegetation is composed of a small number of species that produce high quantities of phytomass. The most common hydrophytes are *P. australis*, *Phragmites frutescens*, *Arundo donax*, *Arundo mediterranea*, and *Typha domingensis*. Large areas of swamps in the Hula Valley supported *Cyperus papyrus*, which reached its northernmost station at this valley. Several rivers of the coastal plain that supported riparian vegetation in the past have become sewage canals and their polluted water has destroyed most of the past rivers' vegetation.

Wet Salinas

Wet, salty soils occur in places in which springs of salty water occur or at sites in which the water table is near the surface and the evaporating water leaves salt in the upper soil layers (Figure 3, 17). A salt crust may occur at the soil surface in arid regions and plants are restricted to small wadis in which leaching occurs. Most plants growing in the desert salt marshes are perennials that establish themselves in the rare event of leaching. The typical plants of desert salty soils are *Suaeda monoica*, *S. fruticosa*, *S. vermiculata*, *N. retusa*, *Seidlitzia rosmarinus*, and a few species of *Tamarix*.

Synanthropic Vegetation

The category of synanthropic vegetation (Figure 3, 18) is further divided in Israel into three subcategories according to

the remnants of trees found in the intensively cultivated areas: In 18a, it is trees of *Q. ithaburensis*, in 18b the tree is *Z. spina-christi*, and in 18c it is *A. raddiana* and *Z. spina-christi*. The synanthropic vegetation of Jordan and the current status of the synanthropic vegetation in Sinai need further investigation.

Mangroves

The mangrove of Nabq, eastern Sinai (Figure 3, 19), typically growing in muddy soils of the tidewater, constitutes the most northerly population of *Avicennia marina* on Earth at 28°10' N. This species was recorded even farther from the equator in South Australia at 37° S. The only population found in the Gulf of Suez shares its water, and possibly warmth, with the Gulf of Elat at Ras Mohammed.

Glossary

Beringia A region at the northwestern corner of North America separated from Asia only by the shallow waters of the Bering Strait. When ocean levels decline during glaciation, Asia and North America are connected by land in this region.

Bioregion A landscape subunit at the scale of the continent that is set apart by its coherent geological and biotic history.

Continental shelf The continental margin, which is submerged to depths of approximately 180 m at current sea levels and is bounded by the abrupt drop to the abyssal depths of the oceans.

Ecoregion A landscape unit within a bioregion in which a distinct assemblage of organisms interacts

ecologically, usually within a spatial context defined by drainage systems, mountain ranges, or similar natural boundaries.

Holarctic A biotic realm in the temperate, boreal, and arctic regions of the Northern Hemisphere with strong affinities among the regional floras and faunas.

Neotropics A biotic realm in tropical South and Central America with strong affinities among the regional floras and faunas but different from the tropical biota of Africa and Southeast Asia (the Paleotropics).

Physiography The landforms that lend shape and character to the continental landscape, for example, the configuration of mountains and drainage basins.

Continental Diversity

Mainland North America, with an area of 24,258,000 km², accounts for 16% of the land surface on Earth and stretches over 65° of latitude. The ancient core of North America is well over 3 billion years old, but parts of the continent are much younger. The continent is bounded on the west by a series of mountain ranges along the coast of the Pacific Ocean. A more extensive coastal plain and less rugged mountains characterize the Atlantic coast of North America. The Arctic Ocean lies at the northern limit of the continent, which includes the extensive Arctic Archipelago. Rugged mountains mark the commonly accepted limit of the continent in southern Mexico, but in fact distinguishing the boundary in this mountainous and geologically complex region where North America grades into Central America is arbitrary. The continental interior is an extensive plain with relatively little topographic relief, although highlands, escarpments, and erosional features occur regionally. Major drainage systems flow both north and south from the interior and also through the Great Lakes basin to the east. The Mississippi River system flowing south into the Gulf of Mexico is among the largest drainage basins in the world. The Caribbean Sea lies southeast of the continent. North America has a land connection to South America through the Isthmus of Panama, a link that formed only approximately 3 million years ago (Ma). In the past few million years, as ocean levels have fluctuated during glacial cycles, there has also been an intermittent land connection to Asia through Beringia. People arrived in North America by this route, and perhaps others, only very recently – sometime in the past 15,000–35,000 years. With the exception of Antarctica, the Americas were the last of the continents to be colonized by people. Although recently much influenced by people, the biota of North America evolved for hundreds of millions of years without a human presence. The current diversity of the

continental biota is founded on this long period of geological and evolutionary history.

Two biological processes interact over millions of years in the evolutionary history of the continental biota: speciation and extinction. Populations, isolated from one another by changing landforms or climates, diverge to form new species. Species become extinct in the face of changing environments or by chance events in small populations. The number of native species in a continental biota at any point in time reflects in part an ongoing balance between speciation and extinction on the continent as a whole. The evolutionary history of a continent is intimately interwoven with its geological history, especially through the influence of continental drift. In the 400 My since life appeared on land, interchange among different continental biota has been possible whenever continents have drifted into contact with one another. Species that have evolved separately on other continents have had opportunities to disperse and colonize North America. This occasional mixing of continental biota together with *in situ* evolution in North America has created the total pool of native species on the continent today. Although this pool of species defines the current magnitude of diversity in North America, the regional patterns of diversity are set by the different distributions of individual species within the continent. Some regions have more species and others fewer. The range of a species within a continent reflects both environmental requirements and the ability to disperse to suitable environments. Species differ in their rates of dispersal and establishment in the face of changing environments and in their ability to cross barriers such as mountains, bodies of water, or inhospitable habitat. The physiography of the continent is thus an important influence on the current patterns of species diversity within North America. Species distributions also depend on climatic patterns within the continent, which arise from both the local influence of physiographic features and the global patterns of

atmospheric circulation from season to season. In the end, the complement of species found in a region depends on the ability of species to disperse to the region, establish there, and survive and reproduce there. Ecological processes acting on relatively short timescales (years to millennia) are the proximate controls on species distribution, but the availability of the species and the distribution of suitable habitats on the continent ultimately have arisen in geological and evolutionary processes acting over much longer timescales (millions of years). It is this interplay of processes on ecological and evolutionary timescales that affects the natural patterns of diversity in North America.

Terrestrial Bioregions of North America

Mainland North America and its offshore islands can be divided into six bioregions: (1) the Canadian Shield in the north, (2) eastern North America, (3) western North America, (4) southwestern North America, (5) a northern extension of the Central American biota in southern Mexico, and (6) outliers of the Caribbean biota on the southern tip of the Florida peninsula. **Figure 1** illustrates and depicts in a general way the boundaries of these six terrestrial bioregions in North America. There is, of course, substantial physiographic and biotic diversity within each bioregion, and the boundaries between adjacent bioregions are not precisely identifiable. Fairly distinct ecoregions can be recognized at smaller spatial scales within each bioregion, and these are important for understanding and conserving biodiversity (Abell *et al.*, 1999; Ricketts *et al.*, 1999). Larger drainage systems, such as that of

the Mississippi River and its tributaries or the Great Lakes basin, subsume many terrestrial ecoregions. The geography of the terrestrial versus freshwater biota of North America differs at the scale of ecoregions and to some degree at the scale of the continental bioregions. Similarly, the recognition of bioregion boundaries at the current continental margins is arbitrary. Continental watersheds are directly linked ecologically to the marine diversity of the continental shelf, and this shelf typically shares a geological history with the adjacent continent. Despite these uncertainties in the boundaries and internal structure of the six bioregions, each does have a reasonable coherence in its geological history, current physiography, and current biota. These bioregions therefore provide a useful working framework in which to summarize the general patterns of terrestrial and freshwater species diversity within North America.

The first three of these bioregions are part of the Holarctic, a zonal assemblage of flora and fauna that has coherence across the whole of the middle and higher latitudes of the Northern Hemisphere. Species may differ among North America, Europe, and Asia, but many families and genera of plants and animals are represented throughout the Holarctic. Higher latitudes within the Holarctic realm, including the Canadian Shield, have especially strong biotic affinities. High-latitude sites in North America, Europe, and Asia are in close proximity around the polar region and share common climatic regimes; biota can disperse and establish among these high-latitude regions more easily than they can move between the more distant and climatically disparate latitudinal extremes within North America. The biota at midlatitudes in the Holarctic, however, are more strongly influenced by

Figure 1 Schematic diagram of the six terrestrial bioregions of North America.

longitudinal climatic gradients and longitudinal contrasts in geologic history and physiography. Hence, we distinguish eastern and western bioregions in the midlatitudes of North America, whereas the Canadian Shield bioregion stretches across the top of the entire continent. Some biogeographers, recognizing similar longitudinal differences at midlatitudes on a global scale, divide the Holarctic into the Nearctic and Palearctic regions. North America comprises the Nearctic.

The last three North American bioregions have strong affinities with the Neotropics, the biotic realm to which South America belongs. The biota of equatorial regions does not have the global coherence that characterizes the Holarctic. Tropical regions of Africa and Southeast Asia, which have a flora and fauna that is distinct from that in the Neotropics, are distinguished as the Palearctic. The Caribbean and southernmost North American bioregions are unambiguously Neotropical, basically representing the northern extent of floras and faunas centered on the continent of South America. The southwestern North American bioregion, however, is a mix of Neotropical and Holarctic biota and is one of the most species-rich regions in the world.

Canadian Shield

This bioregion takes its name from the Canadian Shield, which is the ancient core, or craton, of the North American continent. The bioregion and the craton are not geographically identical. The craton extends as basement rock well under the central and eastern parts of the continent, but this does not affect the regional development of the modern biota. The southern boundary of this bioregion is marked by the shift in surface geology from the ancient, crystalline bedrocks of the craton to younger, sedimentary bedrocks. The bioregion actually extends beyond the craton in northern Alaska and the Yukon, even though the bedrock in these western regions is not nearly as ancient. Two major biomes occur with the Canadian Shield bioregion: the boreal forest and the arctic tundra.

Tundra occupies the coasts and islands of the Arctic Ocean and higher elevations in interior Alaska and the Yukon. These barren lands, with a short, cold growing season, are relatively poor in plant and animal species. From one ecoregion to another within the Canadian Shield bioregion, there are only 100–750 plant species in tundra. Some tundra ecoregions have as many as 50 mammal and 160 bird species, and from 0 to 75 butterfly species, but very few have any reptile or amphibian species. There are usually only approximately 5–25 fish species in tundra. Tundra diversity decreases seasonally as birds migrate to more southern bioregions for the winter. The most diverse tundra biota occurs at high elevations in the Wrangell–St. Elias Range in southern Alaska and the adjacent Yukon. The least diverse tundra occurs along the coasts of the heavily glaciated Axel Heiberg and Ellesmere Islands, both of which extend north of 80° N latitude. There are only approximately 110 species of vascular plants in this northernmost part of North America.

The boreal forest, which occupies the more southern parts of the Canadian Shield bioregion, generally has greater biodiversity than the tundra. Different boreal ecoregions have

between 250 and 1250 vascular plant species that include 5–30 tree species. There are never more than 10 coniferous tree species in any ecoregion, even though conifers dominate much of the boreal landscape. Ecoregions in the boreal forest usually have approximately 20–50 mammal species, 105–185 bird species, 35–95 butterfly species, and 2060 fish species. Amphibians are less diverse, usually 1–5 species in an ecoregion and occasionally more than 10; there may be 1–3 reptile species, but often there are none in a given ecoregion. The boreal forests of central and eastern Canada are the most diverse overall, and those of Newfoundland are the least diverse.

Eastern North America

The Appalachian Orogeny essentially created the character of this bioregion. These mountains on the eastern margin of North America arose approximately 300 Ma in the collision of all the ancient continents to form the supercontinent Pangea. The Appalachians are in fact a part of the African continent left behind as the mid-Atlantic Rift developed beginning approximately 240 Ma, gradually breaking up Pangea, creating the Atlantic Ocean and moving Europe, Africa, and the Americas to their current geographic positions. As the young and rugged Appalachians eroded, huge deposits of sediment accumulated in the continental interior, forming the bedrock of much of the interior plains that comprise the central part of this bioregion. Their sedimentary deposits also account for an extensive continental shelf, rich in marine biota today, and also an important corridor for plant and animal migrations during and after glacial peaks when ocean levels are low. From approximately 170 to 70 Ma, much of the more western interior of this bioregion lay beneath shallow continental seas in which marine biota built up extensive reef systems and sediments. The Canadian Shield forms the basement rock of essentially the entire bioregion, but it is these much younger mountains and sedimentary features that influence the current patterns of biodiversity.

The eastern parts of this bioregion are generally forested with some combination of conifer and broadleaf trees. The western parts are more often grasslands, except for gallery forests along watercourses. The transition from forest to grasslands, which is more a mosaic dependent on local topography and drainage than a smooth gradient, generally occurs to one side or the other of the Mississippi River. Savannas, grasslands with a scattering of trees, are common in the transitional ecoregions. Many of these transitional ecoregions, such as the Edwards Plateau in Texas, have exceptionally high biodiversity. There are approximately 650–3350 species of plants in the different ecoregions of eastern North America, 30–85 mammals, 160–270 birds, 5–65 amphibians, 5–85 reptiles, 75–230 butterflies, 40–230 fish species, 2–260 land snails, 5–125 mussel species, and 1–65 crayfish. The mixed forests of the southeastern US comprise the ecoregion most rich in plant species within eastern North America, and the Pine Barrens of the Atlantic Coastal Plain are the least rich. The western short grasslands are richest in mammal species, and the Florida Pine Scrub is the least rich. These western short grasslands also have the most butterfly species in this bioregion, whereas the lowland

forests of the Gulf of St. Lawrence have the least. The grasslands of the western coast of the Gulf of Mexico are the most rich in bird species, and the Nebraska Sand Hills are least rich. Very high numbers of both amphibian and land snail species occur in the forested Blue Ridge and southern Appalachian Mountains. The Tennessee and Cumberland River systems, which drain the unglaciated Appalachian–Blue Ridge region, are the most rich in fish, mussel, and crayfish species of any region in the bioregion; the glaciated, northern parts of the bioregion are most poor in freshwater biota.

Western North America

Western North America is younger and more rugged than the northern and eastern parts of the continent, with some coastal mountains having been created only in the past 1 My. All of western North America was created as the Farallon Plate, which has been squeezed between the Pacific and North American Plates, gradually subducted under the North American Plate. The subduction of the Farallon Plate caused a series of major episodes of mountain building in western North America: the Sonoran Orogeny approximately 245 Ma, the Nevadan Orogeny approximately 150 Ma, the Sevier Orogeny approximately 120–90 Ma, the Laramide Orogeny approximately 70–60 Ma, and the Basin and Range Orogeny approximately 15 Ma. The continued subduction of the Juan de Fuca Plate, a remnant of the now broken-up Farallon Plate, accounts for the current geologic activity in the Pacific Northwest. All this mountain building associated with the expansion of the North American continent has created and defined the essential character of this bioregion. The landscape is physiographically diverse, with a high degree of regional isolation leading to many distinct ecoregions and a biota rich in local endemics.

The mountains that dominate the landscape in the bioregion are predominantly forested, but various grasslands, shrublands, and deserts occur in basins and on plateaus amid the mountains. Between ecoregions, there is a considerable variation in species diversity. There are approximately 450–2550 species of plants in the different ecoregions of western North America, 30–110 mammals, 140–240 birds, 1–20 amphibians, 0–60 reptiles, 5–225 butterflies, 0–50 land snails, 5–60 fishes, 1–5 mussels, and 0–5 crayfish. Plant species diversity is the lowest on the isolated Queen Charlotte Islands and high in the Sierra Nevada, in the Great Basin, and on the Colorado Plateau. The Colorado Plateau and the Sierra Nevada are notably rich in bird species. The Colorado Plateau and the Colorado Rocky Mountains are rich in butterfly species, whereas the Queen Charlotte Islands are very poor in butterfly species. The forested coastal mountains have the most amphibians in the bioregion, and the Colorado Plateau and the Great Basin have the most reptile species. The Siskiyou Mountains, the Sierra Nevada, and the north Central Rocky Mountains are all notably rich in species of land snails. Although low in terrestrial biodiversity within the bioregion, the watersheds of the mountains along the northern Pacific Coast are the most rich in aquatic species; the isolated and arid watershed of south-central Oregon is the least rich. The Colorado Plateau shrublands are the most species-rich ecoregion

overall, whereas the Queen Charlotte Islands and the adjacent northern Pacific Coast are the most species poor.

Southwestern North America

Northern and central Mexico and immediately adjacent parts of the American Southwest form a distinct bioregion within North America, which, like western North America, has rugged and relatively young terrain. The Sierra Madre Occidental and Sierra Madre Oriental running down the western and eastern coasts converge on a belt of high mountains of volcanic origin in southern Mexico, which form a natural boundary at the southern limits of this bioregion. These mountainous regions surround an interior plateau that grades north into increasingly arid deserts. The mountain ranges stand in contrast to the low relief of the coastal plains along the Pacific Ocean and the Gulf of Mexico and to the Baja California Peninsula. Ecoregions in southwestern North America are especially rich in bird, mammal, reptile, and butterfly species. Among the ecoregions, bird species number 90–280, mammals 50–110, reptiles 10–105, fishes 10–50, and there are at least 130–260 butterflies. Numbers of plant species are also high – 1500–4000 species among the ecoregions – but there are as many as 8000 species along the Sierra Madre Oriental. Not surprisingly, given the aridity of this bioregion in general, the diversity of amphibians is low – only 5–20 species in most ecoregions. There are insufficient data to designate an ecoregion that is the most rich in biodiversity overall, but the more diverse ecoregions are almost certainly in Mexico as opposed to the southwestern US.

Southernmost North America

The tropical highlands of the Sierra Madre del Sur and the Sierra Madre de Chiapas and the tropical lowlands on the Pacific and Gulf Coasts of Mexico comprise this bioregion, which is located at the southern limits of North America. This part of North America has a complex and poorly understood geological history involving the convergence of five plates and various crustal fragments of uncertain continental affinity. It appears certain, however, whether the rugged mountains of Central America and the land connection between North and South America have developed only in the past 2–5 Ma. For the preceding 70 Ma or more, North and South America had been separated by an ocean channel deep and wide enough to severely limit biotic exchange between the two continents. Once Central America arose as a bridge between the two continents, its biota was enriched by migrations in both directions, but especially by Neotropical flora and fauna from South America that were well suited to its tropical climate. Most ecoregions in this part of southern Mexico have in the order of 8000 plant species, although this decreases to only approximately 2000 in the Yucatan Peninsula, where water quickly drains deep underground in the karst landscape. Some ecoregions have as many as 125 amphibian species, but most have only 10–30. Many ecoregions have as many as 120–160 reptile species, 100–300 bird species, and 80–160 mammal species. The overall diversity of this bioregion is high and increases toward the south as the influence of the South

American biota strengthens. Defining the southern limit of North America at the Isthmus of Panama would considerably increase the biodiversity of the continent as a whole.

Caribbean

The Caribbean Plate has a poorly understood geological history. Most of the plate is submerged in a shallow sea dotted with island arcs that are closest to North America at the Florida Peninsula. The southern tip of Florida, the only part of North America that is located in the Caribbean bioregion, has a biota that is a mix of continental and Caribbean elements. There are approximately 1000 species of plants, 25 species of mammals, 175–200 species of birds, 15–20 species of amphibians, 45–50 species of reptiles, 130–135 species of butterflies, and 60–65 species of land snails. Despite the addition of Caribbean species, the biota is not exceptionally rich compared with adjacent parts of the continent.

Diversity in Major Groups of Organisms

An alternative perspective on the general levels and patterns of biodiversity in North America is to focus on the distribution of species in particular taxonomic or functional groups of organisms. Although our knowledge of the biodiversity of North America is better than that for many other parts of the world, it is far from complete and we can only adopt this perspective for the better studied organisms in North America. A few groups of vertebrate animals have been fairly well studied, but the diversity of even these is poorly known in parts of Mexico. Some groups of insects and vascular plants have been fairly well studied throughout the continent, but the sheer numbers of species in these groups undoubtedly indicate that many have yet to be discovered and properly mapped. Well-founded summaries of diversity in microbial groups, many invertebrate animals, fungi, and nonvascular plants currently do not exist for North America as a whole. Despite our incomplete knowledge of North American diversity in individual groups of organisms, the numbers of species and distributional patterns in the better known groups yield insights and provide guidance for conservation efforts.

Plants

There are approximately 1320 species of mosses in North America north of Mexico and approximately 1200 species known from Mexico. The liverworts and hornworts in North America north of Mexico number approximately 650 species, with about 800 species known from Mexico. All these numbers are expected to increase as the continental bryoflora is better explored. There is no comprehensive North American flora for these plant groups.

The pteridophytes (ferns, horsetails, club mosses, spike mosses, and quillworts) are among the most primitive vascular plants represented in the North American flora. There are approximately 440 species of pteridophytes in North America north of Mexico, more than 75% of which are ferns. Mexico has in the order of 1000 pteridophytes species, most of which

are ferns of moist habitats and Neotropical affinity. For example, there are only approximately 125 pteridophyte species in the Chihuahuan Desert of northern Mexico compared with almost 700 species in the southern state of Oaxaca. The moist, tropical forests of southern Mexico harbor the greatest diversity of pteridophytes in North America.

The gymnosperms, an ancient group of plants that includes the pines, spruces, and other conifers, are commercially important and especially well known in North America. There are approximately 90 conifer species in North America north of Mexico; the numbers of conifers in Mexico are higher but uncertain. The well-studied pines of Mexico offer one specific point of comparison with the rest of North America. There are approximately 35 pine species in North America north of Mexico, and only about one-third of these have ranges extending into Mexico. There are another 60 species of pine in Mexico! However, there are 11 spruce species in North America, but only two occur in Mexico. The frequently isolated, arid mountain habitats of Mexico clearly have provided a center for the evolutionary diversification of pines in North America. North of Mexico, the greatest concentration of conifer species is found in the Klamath–Siskiyou ecoregion on the mountainous coast at the California–Oregon border; approximately 30 species of conifer are found there. Conifer diversity is generally greater in the western mountains than in eastern or northern North America.

Trees in general, angiosperm as well as gymnosperm species, have been well studied in North America. There are approximately 650 native species of trees in North America north of Mexico, approximately 85% of which are angiosperms; the arboreal flora of Mexico is not known with certainty but there are at least as many, and probably substantially more, tree species as there are in the rest of the continent. The oaks, which have been well studied in North America including Mexico, provide a useful point of comparison. As many as 150 species of oaks are known from Mexico, approximately 30 of which are also found farther north. There are only about 60 additional oak species in the rest of North America. The Mexican oaks predominate in arid habitats, with the mountains of central and eastern Mexico being a center of diversity. The center of tree diversity north of Mexico is in the southeastern US, where as many as 190 tree species can be found in a given ecoregion. With the exception of Mexico, the diversity of hardwood species declines steadily to the west and north of this concentration of species in the southeastern US.

The angiosperms, both herbaceous and woody, are the most recently evolved and most species rich of the vascular plant groups in North America and indeed throughout the world. The angiosperms comprise the largest part by far of any regional flora. They are also the least completely identified and mapped in terms of their North American patterns of biodiversity. There is no comprehensive floristic inventory for North America, only a series of regional descriptions. There may be as many as 17,000–20,000 native plant species in North America north of Mexico. At midlatitudes, the highest diversity of angiosperm species in an ecoregion is in the forests of the southeastern US, where there are approximately 3000 native angiosperms; species diversity decreases to the west and north on the continent but increases dramatically in Mexico. The state of California, which includes many diverse

ecoregions, has more than 5000 native plant species. The whole of Canada has about only 3125 native angiosperm species, and the Canadian Arctic Archipelago has only 330. Mexico, however, has approximately 19,000 angiosperm species; the state of Oaxaca alone has about 8000. Mexico has approximately 2600 of the 5500 species in the Asteraceae (sunflower family); there are only 400 native species of Asteraceae in Canada. The Fabaceae (bean family) has approximately 1700 species in Mexico, with more than half occurring only in Mexico, compared with only about 130 in Canada. The 900 species of Cactaceae (cacti) in Mexico represent more than half the species in the world. The greatest angiosperm diversity in North America can be clearly found at the southern end of the continent.

Butterflies

There is no reliable estimate of the total number of butterfly species in North America. Comprehensive surveys of western and southwestern North America report only approximately 530 species of butterflies, although this is believed to be from the part of the continent north of Mexico where butterfly diversity is greatest. Surveys of remnant prairie in the mid-continent yielded only approximately 90 species of butterflies, but the prairie ecosystems have been much disrupted in the past 200 years. There are estimated to be approximately 2200 butterfly species in Mexico, and it is certain that butterfly diversity within North America is greatest in Mexico. The swallowtails (Papilionidae), which are among the more conspicuous and better known butterflies, provide evidence of the relative richness of the Mexican butterfly fauna. There are almost 60 swallowtail species in Mexico, about twice as many as in the more northern parts of the continent.

Land Mammals

There are approximately 4500 mammal species in the world. Canada has approximately 140 species of mammals, whereas the US has about 350 and Mexico about 440–450. There is no good composite estimate for the continent as a whole. North of Mexico, the Colorado Plateau harbors the greatest diversity of mammal species but the Chihuahuan Desert, which extends into Mexico, is equally rich in mammal species. The species richness of mammals in North America decreases steadily to the north, and at midlatitudes, it is relatively low in the east compared with the west.

Birds

There are approximately 9000 bird species in the world. Canada has approximately 425 species of birds, the US approximately 650 species, and Mexico approximately 960–1050 species. There is no good composite estimate for the number of bird species on the continent as a whole. The geographic pattern of species richness for birds in North America is generally similar to that of mammals: richest in Mexico and the adjacent southwestern US and steadily decreasing to the north.

Amphibians

The amphibians in North America primarily include frogs and salamanders. There are approximately 4000 amphibian species in the world. Canada has approximately 40 species of amphibians, none of which also occur farther south on the continent. Mexico, in contrast, has approximately 285 amphibian species, approximately 170 of which do not occur elsewhere in North America. The US has approximately 230 amphibian species. There is no good estimate of the number of amphibian species for the continent as a whole. With 55–70 amphibian species, the Appalachian Mountains comprise the region north of Mexico that is most rich in amphibian species, but this is only one-fourth of the number of species in the tropical highlands of central and southern Mexico.

Reptiles

The reptiles in North America include turtles, lizards, snakes, and a negligible number of crocodilians. There are about 6000 reptile species in the world. Canada has only about 40 species of reptiles, none of which also occur farther south on the continent. The US has approximately 280 species of reptiles. Mexico has about 690–720 reptile species, approximately 370 of which do not occur elsewhere in North America. The Chihuahuan Desert is the part of the continent most rich in reptiles.

Freshwater Fishes

North America has approximately 1200 species of freshwater fish. There is, however, a substantial variation in the diversity of fishes in glaciated and unglaciated parts of the continent. The glaciated regions are notably poor in fish species. Canada, despite its very large land area rich in lakes and river systems, has only approximately 180 native fish species. The extensive Hudson Bay Basin, which was entirely glaciated 18,000 years ago, has only approximately 100 fish species and most of these occur in the southern headwaters of the drainage system. The Canadian Arctic Archipelago has fewer than 10 fish species. In contrast, the largely unglaciated Mississippi River Basin has approximately 375 fish species. The southeastern US has 485 freshwater fish species, with the greatest diversity in the Appalachian and adjacent Interior Plateau. Despite the aridity of much of Mexico, about 380–500 freshwater fish species occur there, with notably high numbers of species in the Panuco and Papaloapan River systems along the southwestern coast of the Gulf of Mexico. The arid regions of southwestern North America had wetter climates and more extensive wetland systems as recently as 7500 years ago, but the fish fauna is now restricted to remnant bodies of permanent water. Although the habitats available for fishes in southwestern North America are currently limited, there are many remnant species with a high degree of endemism.

Changes in North American Biodiversity

There is a long history of patterns of biodiversity in North America. The native species that occupy North America today

belong to groups of organisms that have developed over the long history of life on this continent. Some of the earliest life on land is represented by fossil plants more than 400 Million years old that are found along the Acadian coast of North America. The continent has shared in the evolutionary diversification of life on land. Ancestors of conifers in the family Pinaceae grew in what is now North America 135 Ma. Angiosperm fossils from North America date to approximately 120 Ma, near the origins of this now dominant group of plants. Dinosaurs that dominated the animal life of North America beginning approximately 200 Ma are ancestors to the modern birds; the mammals rose to dominance beginning 65 Ma with the mass extinction of dinosaurs. Primitive insects are among the earliest fossils of terrestrial life in North America, but the rapid increases in species numbers of groups such as the butterflies and beetles that have high diversity in North America today also began only 65 Ma. Patterns of continental drift and climate change during the 400 My that life has been on land have facilitated the exchange of biota from different continents. The strong affinity in the flora and fauna of the Holarctic regions of North America, Europe, and Asia has its origins in the period 170–80 Ma, when these continents were still in close proximity to one another. Similarly, the richness of the Central American flora and fauna in southernmost North America stems in part from biotic exchanges initiated in the past 2 or 3 Ma when the Americas were reconnected by land after 60–70 My of relative isolation from one another. Some contemporary patterns of diversity in North America that we might seek to attribute to current environmental conditions in fact originated in the ancient history of life on the continent.

The influence of past events on contemporary patterns of biodiversity has been most marked during the past 1 My, during which climatic changes associated with glacial cycles have repeatedly disrupted the North American biota. Species ranges in North America have shifted dramatically from glacial to interglacial, and current distributions of species reflect patterns of dispersion from the most recent glacial refugia. The relative poverty of species in the more northern parts of North America in part stems from the failure of some species to disperse back into these glaciated regions in the 5000–14,000 years since the ice melted. Major climatic changes from glacial to interglacial periods have also influenced the biodiversity of unglaciated regions of the continent. For example, during the most recent glacial maximum, parts of western and southwestern North America had a wetter climate. Large pluvial lakes and extensive river systems existed that are now mostly reduced to playas and dry channels. Today, desert pupfish occur only in isolated springs and pools, whereas once they were widespread in extensive lake and river systems throughout the Southwest. Once widespread palms now exist only as remnant populations in isolated canyons. In another cycle of changing climate, such remnant populations may again become common, but now we value them as rare species that enhance the biodiversity of North America. The rich and sometimes peculiar patterns of biodiversity in North America are built on a dynamic history of changing environments and changing species distributions.

In terms of the most recent history of the North American biota, the arrival of humans coincident with the end of the

most recent glacial cycle is especially noteworthy. As the interglacial was beginning, hundreds of the larger animals in North America became extinct. It is difficult to account for these extinctions by changing climate alone, and it appears that human hunting pressures were a significant factor. In a brief period, the mammoths, mastadons, camels, horses, saber-tooth tigers, giant ground sloths, and many other large mammals that undoubtedly were major elements in the functioning of North American ecosystems simply disappeared from the continent. The patterns of biodiversity at the time of European settlement not many thousands of years later must reflect this fairly recent mass extinction as well as the continued influence of the few million aboriginal people who already lived in North America at that time. Whatever patterns of continental diversity we identify, we should not assume that they are independent of ancient human influence.

Human influence on patterns of diversity in North America has increased considerably in the past 500 years. The European colonists consciously or inadvertently brought many new plant and animal species to this continent. Indeed, people continue to introduce species from outside North America, some of which establish and spread to natural ecosystems well beyond the confines of urban or agricultural lands. Approximately 25% of the current flora of Canada consists of alien species; the US has approximately 3700 alien plant species, of the order of 20% of the flora. Approximately 6% of the fishes of Canada are not native species; the US has about 75 fish species native outside of North America and approximately 200 that have been introduced outside their native North American ranges. The fishes currently dominating the ecosystems of the Great Lakes are entirely the outcome of the introduction and management of nonnative species by people. Inadvertently introduced zebra mussels have an altered ecosystem function in the Great Lakes Basin and ousted many native mussel species. Introduced starlings and sparrows dominate the avifauna in many settled landscapes. The landscapes and habitats of large parts of the continent have been drastically altered from preColumbian times. Almost all rivers in the US have had their flow altered by dams or their drainage basin hydrology has been manipulated. Terrestrial habitats reasonably unaltered from preColumbian times now occupy only 48% of North America north of Mexico, and these are largely concentrated in remote mountainous or northern regions. Remnants of natural prairie and forest habitats represent only a few percent of many ecoregions in eastern North America. In western North America, natural habitats are essentially obliterated in the grasslands of central California and in the interior grasslands of the Pacific Northwest. We are faced with the challenge of identifying natural patterns in the biodiversity of our native flora and fauna while the continental biota is increasingly disrupted by the introduction of alien species and the alteration of natural landscapes.

Conclusion

From the preceding discussion, assembled from a variety of sources, one point is most clear: we have really only begun to know the patterns of biodiversity in North America. The biodiversity of no group of organisms in North America is

completely characterized. Some of the groups of organisms discussed in this review have been reasonably well studied, but all are incompletely known. Remote parts of arctic North America are little explored and may yield new species despite the general tendency of species diversity to decrease at higher latitudes. There are unusual habitats in the high arctic that are unlike anywhere else on Earth, such as the mineral-rich hot springs on Axel Heiberg Island that emerge through hundreds of meters of permafrost. Such habitats, which are being studied as analogs for Martian polar environments, may well harbor previously unknown microbial life. The more heavily settled and biologically explored midcontinent seems well known, but every year new localities and range extensions, and even new species, are recorded. The remote and rugged parts of southern North America undoubtedly harbor unknown species even in groups that have been well studied on the continent as a whole. Mexico is recognized as one of the top five countries in the world in terms of the overall levels of biodiversity. By far the most species-rich part of North America, Mexico is ironically the least well studied.

In addition to our incomplete knowledge of species diversity in well-studied groups of organisms in North America, we must recognize that there are many other groups of organisms on the continent whose distribution and abundance are scarcely known. There are almost 91,000 species of insects described from North America north of Mexico, but this number is certainly only a small fraction of the total insect species on the continent. Almost all the insect groups have been too little studied to assemble any sort of meaningful summary of their patterns of continental biodiversity. Similarly, there may be as many as 120,000 species of microfungi in the US alone, only one-fourth of which have been described, and far fewer have been studied sufficiently to map and inventory them for the continent. The 5000–10,000 species of macrofungi (mushrooms) estimated to occur in the United States are only marginally better known. It is too early to write the definitive treatise on patterns of biodiversity in North America. There is much exciting and worthwhile work yet to do.

Glossary

Convective mixing Vertical mixing produced by the increasing density of a fluid in the upper layer, especially during winter in temperate and polar regions.

Euphotic zone The surface layer of the ocean in which there is adequate light for net positive photosynthesis.

Nutrients Dissolved mineral salts necessary for primary productivity and phytoplankton growth: Macronutrients are phosphate, nitrate, and silicate; micronutrients are iron, zinc, manganese, and other trace metals.

Phytoplankton Photosynthetic, usually single-celled, plants that drift with ocean currents.

Pycnocline The layer in which density changes most rapidly with depth and separates the surface mixed layer from the deep ocean waters.

Southern Ocean The circumpolar ocean in the Southern Hemisphere between the Subtropical Front and the continent of Antarctica.

Stratification The formation of distinct layers with different densities; stratification inhibits mixing.

Subpolar Pertaining to the regions between the polar and temperate zones, but for the oceans the boundaries are the Subtropical Front and the Polar Front.

Subtropical Pertaining to the regions which, under the influence of the trade winds, are permanently stratified.

Upwelling Upward vertical movement of water through the bottom of the surface mixed layer produced by a divergence at the surface.

Zooplankton Animals that float or drift with ocean currents: Microzooplankton are protozoan plankton that graze on small phytoplankton; mesozooplankton are crustaceans that graze on larger phytoplankton such as diatoms.

History of the Ecosystem Concept

Natural scientists have long recognized that beyond populations or communities there is a higher level of organization, but it has been difficult for physical and biological scientists to reach consensus about its nature. The origins of the ecosystem concept are indistinct and, indeed, involved polemics between some of the principals. Ernst Haeckel (1838–1919) coined the word “ecology” and he envisioned ecology as a science that studies the environment as a stage within which selection pressures and adaptations affect the evolution of species. Haeckel brought the physical environment to the forefront, but he was interested primarily in evolution, which acts on species or genetically interacting populations. Victor Hensen (1835–1924) coined the word “plankton” to describe the organisms that drift in the ocean following the paths dictated by currents and mixing. Hensen was interested in the integrated working of natural systems, the subject today called “ecosystem science.” He was particularly interested in the functional behavior of ocean systems from the smallest phytoplankton up

through the food web and leading finally to fish, birds, and marine mammals. Hensen and Haeckel had a long professional dispute which seems ironic today because the eventual synthesis of their ideas by others led indirectly to the ecosystem concept.

The linguistic route to the modern word “ecosystem” was tortuous. From 1877 to 1939 the words “biocoenose,” “microcosm,” “naturkomplex,” “holocen,” and “biosystem” were all proposed as names for this idea. In 1935 an English scientist, Tansley, introduced the neologism “ecosystem” and this term rapidly eclipsed competing names, but ecosystem science was not a well-organized endeavor until 1959, when Eugene Odum and Howard Odum published a groundbreaking textbook, *Fundamentals of Ecology*. There were many treatises on ecology before the Odums’ book, but their book stressed the principle that the ecosystem (not the population or community) is the fundamental unit of ecology and indeed of biology. The 1959 text, which develops this concept in each of its chapters, has remained in print for many years. Although Eugene Odum’s definition of ecosystem (given at the beginning of this article) is widely accepted, the principle of the ecosystem as the

fundamental unit of ecology is controversial. Populations, communities, adaptation, and evolution have all been explosively successful research areas. Ecosystem research, because of its inherent complexity and requirement for interdisciplinary work, has not enjoyed the success of the more reductionist areas of ecological research. The study of ecosystems is usually supported by encouraging words, but our institutions and agencies, which are organized along disciplinary lines, have trouble coping with a science composed of equal parts of physics, chemistry, and biology. Ecosystem studies are placed with the life sciences, in which there is little institutional or agency enthusiasm for the complex and expensive atmospheric and physical oceanographic work required by the study of ocean ecosystems.

Utility of the Concept

The ecosystem concept was originally developed for terrestrial, intertidal, and benthic habitats, in which ecological succession on timescales of 10–100 years is an obvious and salient characteristic of the ecosystem. Succession on this timescale is difficult or impossible to detect in the fluid medium of pelagic ocean ecosystems. In the ocean, winds, mixing, and currents appear to reset the successional time clock to time zero each annual cycle or, perhaps, with each storm or passage of a front or large eddy. It has been shown that there are low-frequency (over the timescale of 10–100 years) changes in species abundance and community structure. These biological changes are sometimes so far reaching that they are called “regime shifts,” the term used by John Steele in 1998, but they are not functionally analogous to succession, which is (i) orderly and directional, (ii) involving biological modification of the physical environment, and (iii) resulting in a more stable climax community (Odum, 1969). Succession in ocean ecosystems is dramatically evident on the day to month timescale after spring stratification in temperate and subpolar waters or after an episode of upwelling. This short timescale succession, which appears to be cyclic, is not unidirectional and definitely not orderly.

If long-term directional succession does not appear to occur in pelagic ocean ecosystems and succession is a central tenet of ecosystem theory, isn't the very existence of ocean ecosystems in doubt? The answer is that ocean ecosystems, as Steele (1985) noted, are clearly different from terrestrial, aquatic, intertidal, or benthic ecosystems, but ocean ecosystems meet most of the requirements of the definition set forth by Eugene Odum. The ocean ecosystems described here all have a characteristic and distinct trophic structure, characteristic and distinct material cycles, some degree of internal homogeneity and commonality, and definable hydrographic boundaries.

There is considerable heuristic power in the ecosystem concept because understanding gained in one ocean ecosystem can be used to predict the response of another ecosystem of the same kind that is geographically distinct from it. This predictive power is perhaps the greatest benefit of ecosystem theory and provides evidence that each distinct kind of ocean ecosystem has characteristics that can be generalized and used in prediction.

Pomeroy and Alberts (1988) emphasized that the concept involves emergence of new properties. One consequence of the hierarchic organization of ecosystems is that as

components (both biotic and abiotic) are integrated into a larger functional unit, new properties emerge that cannot be detected by study of the component populations or processes, no matter how thorough the reductionist study. This aspect of ecosystem theory makes the concept useful, even necessary, for predictive understanding of ocean ecosystems.

Determining specific emergent properties of a system as large as ocean ecosystems is difficult. Ocean ecosystem spatial domains of thousands of kilometers are difficult to sample adequately with ships; however, with satellites that measure wind, ocean temperature, ocean currents (from sea surface topography), and phytoplankton biomass, a new era has begun in understanding ocean ecosystems. Are there appropriate benefits to justify the large societal investment in remote sensing and data handling required to achieve this new level of understanding? One benefit deals with fisheries management. The historic approach to management of these fisheries has involved analysis of local populations and environment. It has become clear that ecosystem properties, especially physical conditions, operating on scales much larger than the range of the exploited population, may be responsible for changes in reproductive success and adult abundance. In this context, a valuable societal payoff of understanding ocean ecosystems is improved ability to predict local variations in living resources as shown by Sherman and others in 1986. Odum repeatedly emphasized that ecosystem science and economics are parallel disciplines and expressed regret that they are not perceived as such, particularly by the economic community. Investors and political leaders making policy decisions on resource development need an understanding of the probability, frequency, and intensity of natural variability for realistic economic decision making. In this context, economics and the ecosystem concept are closely related: By understanding the variability of ocean ecosystems, decision makers will also understand that variation in marine resources is a normal and inevitable characteristic that must be accommodated in economic plans. This kind of resource-related benefit, although important, is not the only societal benefit that will accrue.

Odum (1977) said, “It is the properties of the large-scale integrated systems that hold solutions to most of the long-range problems of society.” Although few in the scientific community recognized the wisdom of this comment two decades ago, the validity of Odum's prediction has now been well demonstrated. For example, carbon dioxide modification of the planet's heat budget, and therefore climate, is a phenomenon that can be understood only if the emergent properties of large-scale biogeochemical systems are understood.

Partitioning the Ocean into Natural Functioning Units

Central Problem

The central problem for the lower trophic level of ocean ecosystems is obtaining light (energy) and inorganic nutrients (mass). Odum's definition requires that for a functioning system to be a distinct ecosystem it must possess characteristic trophic structure and material cycles. That is, how one kind of ocean ecosystem captures light and passes that energy on in

the form of primary productivity, secondary productivity, and so forth is different from how another kind of ocean ecosystem processes and transfers its energy. Likewise, how mass (C, N, P, and Si), initially in the form of inorganic compounds, is taken up and transferred through the food web and eventually released back to the environment is different and very poorly understood.

What controls the supply of light and nutrients to an ocean ecosystem? Sverdrup in 1955 was the first oceanographer to note that the spatial and temporal patterns of physical processes, particularly the seasonal patterns of mixing, stratification, and upwelling as well as the seasonal pattern of irradiance, control the patterns of biological organization. The division of ocean ecosystems into six distinct types is based fundamentally on the pioneering work of Sverdrup and that of others in the intervening years.

Biome Concept

Longhurst (1998) presented a scholarly discussion of the attempt to partition the oceans into natural functional provinces. He described with considerable élan a regional ecology of the oceans which is clearly distinct from partitioning the ocean into ecosystems. The difference can be illustrated using one of the best described ocean ecosystems, the coastal upwelling ecosystem. It is well accepted that there is one coastal upwelling ecosystem and that it is replicated at five coastal regions in the world ocean: the California Current off California and Mexico, the Peru Current off Peru and Chile, the Benguela Current, the Canary Current, and the Arabian Sea off Oman and Yemen. Longhurst recognized the same regions but counted them as five distinct ocean "provinces." The ecosystem concept emphasizes that there are geographic ocean regions that have much in common; ecological geography emphasizes the discreteness or autonomy of various ocean provinces. Both concepts are useful.

Longhurst (1998) proposed that the following information is required to define the functional nature of an ocean region:

Latitude, which determines if wind stress induces mixing or wind-driven advection

Depth of water because stratification may be broken down in shallow seas by tidal mixing

Proximity to coastline, which determines the effects of terrestrial runoff, river discharge, and release of nutrients (especially Fe) from sediments

Seasonal irradiance, which forces photosynthesis, stratification, and freezing or melting of ice

Winds, which force mixing or upwelling of subsurface waters and their nutrients up to the euphotic zone

Precipitation, which may induce strong stratification by making the surface layer less salty

Nutricline depth, which modifies the vertical flux of nutrients by wind mixing and upwelling

Strength of the vertical nutrient gradient, which determines the magnitude of the upward nutrient flux

External source of iron, because insufficient iron may limit uptake of macronutrients, phytoplankton growth, or primary productivity

Using these criteria, Longhurst partitioned the ocean into four major biomes: the westerlies biome, in which convective mixing and stratification are forced largely by the strong seasonal progression of winds, irradiance, and heat flux; the trades biome, in which upwelling and mixing are forced on the ocean-basin scale by both local and remote wind forcing; the polar biome, in which there is no significant thermal stratification and mixed layer depth is constrained by a surface low-salinity layer which forms each summer as the marginal ice melts; and the coastal biome, in which coastal processes such as tides or currents break down stratification and force mixing.

Longhurst's (1998) partitioning of the ocean into four biomes and 55 provinces is a significant accomplishment. Eventually, his ideas will be merged with the ecosystem concept to produce an internally consistent hierarchy of biomes, ecosystems, and provinces.

Ecosystem Concept

Using the formal Odum definition of ecosystem, six more or less well-defined ocean ecosystems can be delineated (Table 1), but note that the boundaries of these ecosystems are usually oceanographic, not geographic, features. (See Tomczak and Godfrey (1994) for a description of these oceanographic features). Although it is possible to describe approximately where these ecosystems exist, the actual domain is determined by dynamic processes such as fronts where two kinds of ocean water converge. The approach is to define the characteristic trophic structure and material cycles by applying the same analysis to each system. Each of the six systems has a different combination of stratification, nutrient supply (Table 1), primary productivity (Table 2), and biotic characteristics (Table 3). This analysis indicates that there are six distinct ocean systems that meet Odum's criteria:

1. A low-latitude gyre ecosystem is present in each of the five great low-latitude gyres—North Atlantic, South Atlantic, North Pacific, South Pacific, and South Indian Oceans—as well as in the warm pool of the western Pacific Ocean, the equatorial Indian Ocean, and in large marginal seas such as the Mediterranean Sea and the Gulf of Mexico. This ecosystem is also present in the Western Boundary Current regions between the western edge of each of the five great gyres and the coastal waters of the adjacent continent.
2. The Southern Ocean ecosystem occupies the circumpolar area between the continent of Antarctica and the Subtropical Front at approximately 40° S latitude; the Southern Ocean ecosystem has a subantarctic region from the Subtropical Front south to the Polar Front and an Antarctic region from the Polar Front to the Antarctic continent.
3. The equatorial upwelling ecosystem occupies an equatorial band from 5° N to 5° S and from South America westward to 180° in the eastern and central Pacific Ocean. This region is often called the "cold tongue" because upwelling keeps these tropical waters surprisingly cool. In the Atlantic the 5° N to 5° S band of equatorial upwelling reaches from Africa across to South America. In the Indian

Table 1 Summary of heat flux, stratification, nutrient, and light characteristics of ocean ecosystems

<i>Oceanecosystem</i> ^a	<i>Heat flux</i>	<i>Stratification</i>		<i>Nutrient</i>		<i>Light</i>	
		<i>Strength</i>	<i>Duration</i>	<i>Level</i>	<i>Source</i>	<i>Level</i>	<i>Pattern</i>
Low-latitude gyre	Neutral; negative in Western Boundary Current	Strong	Permanent	Low ($\ll K_S$) ^b	Eddy diffusion, very weak convection	High ($\gg E_k$) ^c	Continuous
Southern Ocean	Negative (ocean loses heat)	Very weak, except strong when ice melts in summer	Seasonal	High ($> K_S$), except Si(OH)_4	Mixing and upwelling	Moderate in summer; low rest of year	Strongly seasonal
Equatorial upwelling	Positive (ocean gains heat)	Strong stratification following vertical transport	Permanent	High ($> K_S$), except Si(OH)_4	Upwelling and mixing	High ($\gg E_k$)	Continuous
Subarctic gyre	Seasonally positive and negative	Moderate stratification following winter mixing	Seasonal convective mixing	High ($> K_S$ in winter; $\approx K_S$ rest of year)	Convective mixing and eddies	Low in winter ($\ll E_k$); moderate rest of year ($\approx E_k$)	Seasonal
Eastern Boundary Current	Positive	Medium	Permanent	Medium ($> K_S$)	Upwelling and lateral advection	Moderate ($> E_k$), except in winter	Seasonal
Coastal upwelling	Positive	Strong stratification following vertical transport	Continuous	High ($\gg K_S$)	Upwelling	High ($> E_k$)	Weakly seasonal

^aSee text for the location and boundaries of these ecosystems.^b K_S is the nutrient concentration at which nutrient uptake occurs at one-half the maximal rate; at concentrations $< K_S$, uptake is limited.^c E_k is the light level at which the photosynthetic rate is light saturated; at light levels $< E_k$, photosynthesis is light limited.

Table 2 Summary of size, primary productivity, export, and limiting factors of ocean ecosystems

<i>Ocean ecosystem</i>	<i>Size^a</i>		<i>Primary productivity amount and pattern (mmol C m⁻² day⁻¹)^b</i>	<i>Export ratio^c</i>	<i>Factors limiting primary productivity</i>	<i>Factors limiting fish yield</i>
	<i>Area (m² × 10¹²)</i>	<i>%</i>				
Low-latitude gyre	164	52	35 continuously	Low; weak seasonality	Macronutrients	Low primary productivity, small size of organisms and long food web
Southern Ocean	77	25	120 summer mean; ≈35 in spring and fall; ≈0 in winter	High in summer; very low in winter	Iron and light	Short duration of summer bloom
Equatorial upwelling	22	7	90 continuously	Low continuously	Iron and silicate	Low export productivity
Subarctic gyre	22	7	150 spring bloom mean; ≈50 rest of year	Episodically high; moderate rest of year	Depth of winter mixing	Short duration of spring bloom
Eastern Boundary Current	21	7	150 summer mean; 75 rest of year; grades into gyre ≈35	High in summer; moderate rest of year	Unclear, but iron is a factor, and light is also in winter	Unclear
Coastal upwelling	6	2	300 continuously close to coast; grades into Eastern Boundary Current ≈150	High, but spatially variable	Iron	Small size of ecosystem

^aSize was calculated for the world ocean exclusive of noncoastal upwelling, continental shelf regions; total area was $312 \times 10^{12} \text{ m}^2$.

^bBased mainly on recent measurements made by the author in the Joint Global Ocean Flux Study.

^cExport ratio is the relative proportion of primary productivity that is exported vertically, horizontally, or to higher trophic levels. The maximum observed export ratios relative to total primary productivity are approximately 0.50.

Table 3 Summary of biotic characteristics, the zooplankton component of ocean ecosystems

<i>Ecosystem</i>	<i>Endemic spp.</i>	<i>Species richness</i>	<i>Species evenness</i>	<i>Variability of biomass</i>	<i>Size of organisms</i>	<i>Importance of protozoan micrograzers</i>
Low-latitude gyre	Low	High	High	Low	Small	Dominant
Southern Ocean	High	Low	Very low	Very high ($>5 \times$)	Large	Moderate to low
Equatorial upwelling	Moderate	High	High	Low	Small	Dominant
Subarctic gyre	High	Low	Low	High ($>2 \times$)	Moderate	Moderate to low
Eastern Boundary Current	Moderate	Moderate	Moderate	Low ($<2 \times$)	Moderate	Dominant to low
Coastal upwelling	Low	High	Moderate	Moderate ($\approx 2 \times$)	Large	Low

Ocean equatorial region there is no manifestation of this ecosystem because the upwelling, if present, does not extend upwards into the euphotic zone.

4. A subarctic gyre ecosystem is present in both the North Atlantic and the North Pacific in the region north of the Subtropical Front at approximately 40° N. In the Atlantic, the subarctic gyre ecosystem is bounded on the south by the North Atlantic Current and Subtropical Front, on the west by the Labrador Current, on the north by the East Greenland Current, and on the east by Europe. The North Atlantic subarctic gyre is a complex, but very well-delineated, ocean feature. The North Pacific subpolar gyre is bounded on the south at approximately 40° N by the North Pacific Current and the Subtropical Front, on the west by Siberia, on the north by the Aleutian Islands and Alaska, and on the east by Canada.
5. An Eastern Boundary Current (EBC) ecosystem is represented in each of the four great EBCs: the California Current off the west coast of the United States and Mexico, the Peru Current off Peru and Chile, the Canary Current off Northwest Africa, and the Benguela Current off Namibia and South Africa. These locations are characterized by a broad and weak equatorward-flowing current that usually extends offshore 400–600 km. Each of these ecosystems receives upwelled water from a coastal upwelling ecosystem and, in turn, exports water to the adjacent low-latitude ecosystem.
6. There are four great coastal upwelling ecosystems: Peru Current, Benguela Current, Canary Current, and California Current. This ecosystem is narrow but long; it extends for great distances along the west coasts of South America, North America, northwest Africa, and South Africa. This ecosystem is also present in the northwestern Arabian Sea, along the coasts of Oman and Yemen, where evidence of upwelled water is present up to 600 km off the Omani coast.

Characteristics of Ocean Ecosystems

Shared Characteristics

The following characteristics of ocean ecosystems are based on a 1974 synthesis by McGowan for the oceanic Pacific Ocean:

They are few in number (only six). This small number of ocean ecosystems contrasts dramatically with the much larger

number of well-defined terrestrial, intertidal, and coastal habitats that occur in much smaller areas. The reason, of course, is that the fluid medium of the open ocean is fundamentally partitioned by the dominant physical processes that occur in an oceanic area, and there are only a few (six) of these overriding physical patterns. In contrast, terrestrial, intertidal, or coastal ecosystems are fundamentally partitioned by spatial or geographic features and there is a much larger number of unique geographic features associated with the solid surface of the earth's crust. The same fundamental concept pervades all aspects of the comparison of oceanic biodiversity with that of terrestrial, intertidal, or coastal biodiversity. The fluid medium of the ocean is relatively homogeneous, and the boundaries that do exist are dynamic processes such as the presence or absence of winter convective mixing. It is obvious that dynamic processes of this nature form physical boundaries that permit much more biological exchange than the physical barrier associated with the solid earth.

They are large relative to terrestrial, intertidal, or coastal ecosystems. The largest ocean ecosystem, the low-latitude gyre ecosystem, occupies 52% of the open ocean area of the world ocean. This ecosystem's size is a simple reflection of the phenomenon that the earth has vast surface area occupied by the great circulation features called gyres which are slow-turning circular ocean current patterns set in motion ultimately by wind and the rotation of the earth. These gyres, together with the tropical warm pool regions and certain of the marginal seas, occupy a large portion of the earth's surface. Because of the size of the low-latitude gyre ecosystem, it plays an important role in the global heat budget and in exchanges with the atmosphere, and it is the single most important ecosystem for understanding future global change. Ironically and unfortunately, it is one of the least understood ecosystems on Earth. Its size and remoteness from societal activity, especially direct economic activity, have led both scientific and political policymakers to assign the large low-latitude gyre ecosystem a low priority for scientific effort.

On the other hand, the smallest ocean ecosystem, the coastal upwelling ecosystem, has received thorough, comprehensive, and multinational study during the past three decades. This ecosystem is small relative to other ocean systems; it has very strong physical, chemical, and biological processes; it has huge economic importance and considerable geological importance because much of the earth's oil is assumed to have been formed in past upwelling ecosystems. Coastal upwelling ecosystems do have great societal importance, and the global effort to study and understand these

important systems reflects well on the wisdom of scientific and political decision makers.

They are geologically old (with the exception of coastal upwelling). Oceanic cores suggest that the defining oceanographic features have been in place for the past 200,000 years and perhaps for the past 1 million years. The coastal upwelling ecosystem, however, may have disappeared entirely during periods of lower sea level such as during the last Glacial Maximum approximately 18,000 years ago.

They respond to climate but not to weather. Subtle and pervasive changes in mixed layer depth, the depth of convective mixing, or the strength of stratification cause profound changes in ocean ecosystems. On the other hand, strong storms or the passage of a violent hurricane cause no change that is detectable in the ocean ecosystem 2 weeks after the event. El Niño events cause profound changes in equatorial upwelling, EBC, and coastal upwelling ecosystems, but when El Niño ends the lower trophic levels of these ecosystems (phytoplankton, bacteria, microzooplankton, and mesozooplankton) return to their pre-El Niño condition within 1 month. Higher trophic levels, of course, require several years to recover.

They have considerable internal homogeneity, i.e., they tend to be monotonous. The key word is "internal." There are clear changes in almost all biological properties when physical or oceanographic boundaries are crossed; however, if

oceanographic boundaries are not crossed, biological properties will remain surprisingly similar over distances of thousands of kilometers.

They are relatively undisturbed by anthropogenic processes compared to other ecosystems. The largest human disturbance thus far has been ruthless overfishing that removes top predators. The removal of these long-lived and slow-growing carnivores appears to set off a trophic cascade that changes the ecosystem even down to the level of nutrient regeneration by bacteria and protozoa. A second and more threatening change is that as the earth's heat budget changes the processes of precipitation, winter mixing, stratification, and depth of the nutricline all change in such a way that there is less transport of nutrients into the euphotic zone. This change, already apparent in the North Pacific Ocean, will reduce productivity and, hence, the yield of food resources.

The basic organization (Figure 1) is like that of other ecosystems. It appears that the basic assembly rules for all ecosystems are very similar. There has to be a large number of primary producers, somewhat fewer herbivores, still fewer carnivores, and many fewer top predators. There have to be efficient recyclers to return a portion of the nutrients back to the euphotic zone. In addition, the ecological "rules" regarding diversity, species composition, and adaptation are expressed similarly in terrestrial and ocean ecosystems.

Figure 1 Generalized organization of ocean ecosystems. Physical forcing and input functions are shown in dark gray, chemical and geologic input functions are white, and biological components are in light gray. Physical transfers of energy, momentum, or mass are shown by arrows with solid lines; biological transfers of mass and energy between living components are shown by arrows with dotted lines. The export process at the extreme right, labeled fishing, is a proxy for all processes that remove biomass from the euphotic zone of the represented ecosystem.

Distinguishing Characteristics

There are qualitative differences in the basic biological processes. The most dramatic illustration of this is the observation that processes limiting productivity, biomass, export, and yield are different in almost every one of these six ecosystems. Although our understanding of limiting factors may change, currently it appears that the low-latitude gyres are limited by fixed nitrogen, especially nitrate and ammonia; the Southern Ocean appears to be limited by iron and light; the equatorial upwelling ecosystem appears to be limited by iron and silicon; coastal upwelling ecosystem rates appear not to be limited by any macronutrient, but the space where optimal coastal upwelling occurs is highly constrained and iron supply is involved; the EBC ecosystem appears to be limited by light and iron in winter and by iron alone in the summer; and the subarctic gyre ecosystem appears to be limited by the depth of the winter mixed layer or convection.

There are quantitative differences in basic processes such as primary productivity among different kinds of ocean ecosystems. One of the important milestones in the study and understanding of these differences was the work of **John Ryther, who in 1969** published a work that provided a quantitative explanation of why fish yields vary by approximately 200-fold from the richest ocean ecosystems to the poorest. Variations in productivity, of course, are well-known from terrestrial ecosystems, but on land either aridity in deserts or freezing in polar regions is responsible for the low productivity of the poorest regions. Understanding why the benign low-latitude gyre ecosystem was so poor in fish production was much more difficult than understanding why productivity was low in deserts and polar regions. Part of the explanation was proposed in 1955 by Sverdrup, who said simply that the physical supply of nutrients to the euphotic zone is the reason for low fish yields in stratified ocean ecosystems. Ryther's contribution amplified the physical explanation by considering the nature of the ecological processes that lead to fish production.

First, Ryther estimated that approximately half the fish caught in the world are caught in coastal upwelling ecosystems, the smallest of the ocean ecosystems. Why? To begin, Sverdrup was correct: The physical processes of upwelling bring abundant nutrients to the surface layer, so primary productivity is very high in upwelling ecosystems. However, much more is involved. The phytoplankton that thrive in the rich coastal upwelling ecosystems are very large—so large that some are eaten directly by fish. This means that in coastal upwelling ecosystems the food chain leading to fish is very short. Ryther estimated that half the fish diet was phytoplankton and half was zooplankton. On average, then, the length of the food chain leading to fish had 1.5 transfers: large phytoplankton to fish or large phytoplankton to zooplankton to fish. At each ecological transfer, a large portion of the energy of the food is used to support the organism and this portion cannot be passed up the food chain. The shortness of the food chain is a factor that multiplies the high nutrient effect. Ryther also noted that in the small and food-rich coastal upwelling ecosystem the fish and zooplankton did not have to work as hard to get food, so the efficiency of transfer was increased relative to that of a poor environment such as the low-latitude gyre. Ryther proposed that fish yields were high in the coastal upwelling ecosystem

because of high nutrients, high primary productivity, large size of the primary producers, short food chains with few transfers, and increased efficiency of transfer. These effects multiply each other, leading to very high yields of fish. For the same reason, the abundance of seabirds and marine mammals is also very high in the coastal upwelling ecosystem.

The same arguments in reverse explain the low fish yields of the low-latitude gyre ecosystem. The other four ocean ecosystems range between these two extremes. The order of fish yield per unit area can be approximately estimated, from highest to lowest, as (1) coastal upwelling ecosystem, (2) subarctic gyres ecosystem, (3) EBC ecosystem, (4) Southern Ocean ecosystem, (5) equatorial upwelling ecosystem, and (6) low-latitude gyre ecosystem.

Ocean Ecosystems and Global Change

Human intervention in the material cycles and trophic structure of ocean ecosystems may already have caused some changes. The interventions are so varied and play out at so many different scales that it is difficult to know how to describe their impact on future climate change. One approach is to focus on model studies of how anthropogenic ocean warming will affect ocean ecosystems. Considerable effort has gone into investigating how increased atmospheric carbon dioxide will affect the physical ocean-atmosphere system. Other effort has gone into determining how the ocean's carbon dioxide system will behave in an anthropogenically warmed ocean. Today's atmosphere-ocean climate models are fully coupled to an ocean carbon model, including a full carbon system and the biological transfers of the pelagic food web. Results of these model runs are dramatic and, as expected, they predict (i) a warming of global mean sea surface temperature by 2.5 °C, (ii) a slight decrease in light because of increased cloud cover, (iii) a large increase in vertical stratification because of increased precipitation which lowers salinity, and (iv) increased heating of the surface layer. The increase in stratification and decrease in convective mixing are predicted to cause a 37% reduction in the supply of nutrients to the euphotic layer. All physical processes that transport nutrients from the deep ocean reservoir to the surface layer are affected: upwelling, wind and tidal mixing, and convective mixing.

Of the three classes of impacts—warming, light, and increased stratification—increased stratification will have the major impact on ocean ecosystems. The changes predicted vary in intensity from one ocean ecosystem to another, but they are most severe in productive ecosystems such as the subantarctic gyre, equatorial upwelling, and coastal upwelling ecosystems. Very little change in nutrient supply is predicted for the world ocean's five great low-latitude gyres. The predicted change is an expansion of the size of the world ocean's most oligotrophic ecosystems: Approximately half of the ocean area will have decreased nutrient supply; the low-latitude gyres, the poorest half, will have no change; and a very small area (less than 5%) in the high Arctic and Antarctic will have an increase in nutrient flux to the surface.

The El Niño phenomenon has provided evidence of the biological consequences of reducing an ocean ecosystem nutrient supply. New populations that became established under the low nutrient conditions are healthy, highly diverse communities, but they are dramatically different. Another consequence of reduced nutrients is that the biological pump sequesters less carbon dioxide. This change will feed back into the global carbon system to accelerate the increase in concentration of atmospheric carbon dioxide.

A reduction of new nutrients by 37% will have a strong impact on both the quantity and the kind of fish present. Because the increase will occur in what are now rich fishing regions, the coastal upwelling and subarctic gyre, the societal impact will be larger than the biological impact. A change of 37% in new nutrients is significant, but it is not enough to destroy ocean ecosystems. The current gradient in nutrient flux from the low-latitude gyre ecosystem to a coastal upwelling ecosystem region is more than a factor of 10. The predicted changes will reduce the yield from the world's rich fishing banks, but the expanded low-latitude gyre ecosystems should maintain their ecological integrity.

Glossary

Calanoid copepods These belong to the Crustacea and are very abundant in the zooplankton. They play a major ecological role in the food web of the pelagic ecosystem as grazers of phytoplankton and as a food source for, for example, larval and adult fish.

Clupeid fish Pelagic fish, including the anchovy, sardine, and herring, which feed on plankton.

El Niño Southern Oscillation (ENSO) Regarded as quasiperiodic fluctuations occurring in the equatorial region of the Pacific Ocean. The ENSO is associated with changes in the sea surface temperature, sea surface levels, and rainfall patterns in the tropics and with a possible influence on the weather at higher latitudes. ENSO events have also been associated with changes in fisheries and ecosystem processes.

Gadoid fish Includes the cod *Gadus morhua* L.; the life cycle of cod can be summarized as four stages: spawning, larvae, juveniles, and adults. During the larval and early juvenile phases they feed largely on copepods on the nursery grounds; after this phase they become largely stationary and feed on benthic or epibenthic animals.

North Atlantic Oscillation (NAO) The difference in atmospheric pressure between Ponta Delgada, Azores, and Stykkisholmur, Iceland. The variations in the NAO are

usually associated with a positive or negative phase related to changes in the direction and strength of the westerly wind as well as in sea surface temperature. During a positive phase, winters over Scandinavia are warmer and vice versa. Recently, the fluctuations observed in the NAO have been related to changes in ecosystem processes.

Phytoplankton Unicellular photoautotrophic plant cells ranging in size from 1 μm to 1 mm. They are divided into 12 taxonomically defined divisions, including diatoms, dinoflagellates, and coccolithophorids.

Primary production An estimate of the rate of carbon fixation by phytoplankton; this can account for up to 75% of the photosynthetic production on Earth.

Russell cycle Named after F. Russell, the Russell cycle describes a major change in the biota of the English Channel from 1925 to 1972.

Zooplankton From the Greek *zoon* meaning animal, zooplankton comprises those animals that are found passively drifting or weakly swimming in the water column. Zooplankton can be divided into two major categories: holoplankton, which are organisms that spend their entire lives as plankton, and meroplankton, which are organisms that spend part of their life cycle as plankton and part on the seafloor as benthic invertebrate larvae or as nekton (e.g., fish larvae).

Phytoplankton and Primary Production

The etymology of the word “plankton” derives from the ancient Greek meaning wandering. Plankton have very limited motility and are dependent on currents and the physical environment for their location. Phytoplankton comprises a very diverse group of single-celled photoautotrophic planktonic plants that are divided into 12 taxonomic divisions (3500–4500 species of oceanic plankton) and live in the surface water of the oceans. The role played by phytoplankton is at the base of the biogeochemical cycles in the ocean. Species range in size from small prokaryotic and eukaryotic cells comparable to bacteria to larger organisms such as diatoms, dinoflagellates, and coccolithophorids (Figures 1 and 2). A typical phytoplankton community contains a mixture of these, although the species which are dominant vary through time. The majority of the species present in the ocean gain their energy *via* photosynthesis and, therefore, environmental factors such as light availability, temperature, and the supply of major nutrients in the form of ions are important factors that influence their distribution on both temporal and spatial scales. Several hypotheses have been proposed which explain the coexistence of several species; one, “temporal succession,” supposes that the nutrient regime of the environment changes

rapidly so that all species are in different states of approaching to or declining from their maximum abundance. In low-turbulence environments microhabitats may develop which favor the growth of a distinct patch of plankton. Alternatively, different species may be limited in growth by the availability of different nutrients so that coexistence is possible. In neritic temperate waters of the North Sea and in the open temperate North Atlantic, the mean seasonal pattern of phytoplankton abundance shows a distinct peak in the spring, followed by a summer decline and a second, lesser, peak in the autumn. Work by Colebrook (1986) showed a clear differentiation between those species associated with the spring bloom, which tended to be diatoms, and those associated with the autumn bloom, which tended to be dinoflagellates. There were changes in the North Sea in terms of phytoplankton species composition after 1987, for example, *Ceratium* spp. (Dickson *et al.*, 1992) and *Thalassiothrix longissima* (Reid *et al.*, 1992), which signaled a change in the ecosystem. These changes have been related to an increase in the sea surface temperature (SST) and to changes in the extension of the Baltic/Norwegian waters in the North Sea and an increased input of more oceanic water. Variations in the seasonal cycle are caused by different preferences of the groups for light intensity, water stability, temperature, and nutrient availability.

Figure 1 Phytoplankton species illustrating the taxonomic diversity as well as the shape and size of these organisms, which are an important component of the pelagic food web. (a) Diatomophyceae, *Skeletonema costatum*, a worldwide diatom species with distinctive features such as long chains of small cells with long external tubes. Diameter varies between 2 and 21 μm . (b) Dinophyceae, *Ceratium furca*, a worldwide dinoflagellate with a solitary or paired life-form, with a straight body, and the epitheca gradually tapers into an anterior horn. The size ranges in length between 70 and 200 μm and in width between 30 and 50 μm . (c) Dinophyceae, *Dinophysis norvegica*, a solitary dinoflagellate, normally found in cold waters, varies in size with length between 48 and 67 μm and width between 39 and 53 μm . *Dinophysis norvegica* can be regarded as a toxic species since it produces a toxin that causes diarrhetic shellfish poisoning and therefore it is a potentially dangerous species when found in coastal waters in large numbers. (Photos courtesy of Mats Kuylenskierna and Bengt Karlson).

Figure 2 A (SEM) photo of a Haptophyta coccolithophorid, *Emiliana huxleyi*, found worldwide; the diameter varies between 5 and 10 μm , and the coccoliths are $3.5 \times 3 \mu\text{m}$. (Photos courtesy of Mats Kuylenskierna and Bengt Karlson).

A bimodal pattern of the seasonal cycle is evident across the temperate North Atlantic but other patterns exist in different geographical regions. Polar regions show a single summer peak because light intensity is only sufficient for a short period of phytoplankton growth. The north Pacific Ocean shows no spring peak, and in fact there is little change in the phytoplankton standing stock throughout the year. The principal reason is that the dominant zooplankton (the copepod genus *Neocalanus*) overwinter as adults which produce young in the spring without feeding. The young are then able to

Figure 3 An example of a cyanobacteria species, *Synechococcus*, found in the central Skagerrak; the size range is between 1 and 3 μm in length. (Photos courtesy of Mats Kuylenstierna and Bengt Karlson).

immediately take advantage of any increase in the phytoplankton and effectively prevent a spring bloom. The tropics show little seasonality and both phytoplankton and zooplankton fluctuate slightly throughout the year, dependent on local processes. Large blooms of phytoplankton can be monitored *via* satellite remote sensing (e.g., the coccolithophorid *Emiliana huxleyi*). They have the potential to modify, to some extent, the carbon exchange taking place between the ocean and the atmosphere. **Figure 3** shows an example of a cyanobacterium, *Synechococcus* sp., which is an extremely small photoautotrophic cell 1–3 μm in length. Picocyanobacteria and nanoflagellates are responsible for assimilating excretory products of zooplankton consumers in the euphotic zone in nutrient-poor waters characteristic of the central ocean gyres. As noted by Falkowski *et al.* (1998), the fixation of carbon by phytoplankton results in approximately 45 gigatons of organic carbon per year, of which approximately 16 gigatons is exported out of the surface waters. Changes in the total and export production can affect the marine food web structure, ultimately leading to changes in the fish stocks. The photosynthetic pigments such as chlorophyll *a* can be used as a proxy measurement of phytoplankton biomass, and with the aid of satellite-derived measurements a color index can be derived to illustrate changes in primary production. Behrenfeld and Falkowski (1997) generated several maps of primary production estimates for the world's ocean (**Figure 4** and **Figure 5**). Measurements of phytoplankton color on samples taken by the Continuous plankton recorder (CPR) survey from the central northeast Atlantic and North Sea (**Figure 6**) shows a similar increasing trend and longer growing season as that of the satellite-derived vegetation index and this trend dates back to 1948. The phytoplankton increase is not ubiquitous because an inverse trend is evident in eastern Atlantic waters between latitudes 59° N and 63° N. This index of phytoplankton change may reflect a possible long-term

Figure 5 A map of primary production generated when PoptB is estimated using the relationship between temperature and the maximum phytoplankton specific growth rate and modified for photosynthesis (map courtesy of Paul G. Falkowski).

Figure 6 Phytoplankton color distribution from the CPR survey from 1948 to 1995 showing an increase in the late 1980s in the central part of the North Sea and in the central northeast Atlantic coinciding with a change in the NAO index from a negative to a positive phase. A reverse trend was observed for the north-northeast Atlantic (redrawn from Reid *et al.*, 1998, courtesy of SAHFOS, with permission from Nature 391, 546 (1998)).

biological response in the North Atlantic to increasing global temperatures which are causing melting of ice, sea ice, and permafrost in the Arctic (Reid *et al.*, 1998).

In the central North Pacific environment, Venrick (1990) observed 245 species of phytoplankton in the shallow waters and 231 in the deep zone during the period between 1972 and 1985. In both areas, 21 species accounted for 90% of the individuals and most of the variance in abundance occurred at small spatiotemporal scales and samples within a zone were similar. This study showed that epipelagic populations of the North Pacific central environment were more stable when compared with planktonic populations from other ecosystems. In relation to the pelagic food web structure, phytoplankton is an important food source for the larval stage of

pelagic fish and thus plays an important role in the trophic structure of pelagic communities.

Zooplankton

Zooplankton are the secondary producers in pelagic ecosystems and comprise an extraordinarily wide range of organisms. The zooplankton community of continental shelf waters, for example, may contain larval stages of littoral and benthic invertebrates (meroplankton) in addition to the species that spend all their lives in the plankton (holoplankton). Phytoplankton production in these nutrient-rich waters is generally regulated by the grazing activity of zooplankton

(Figure 7). Most zooplankton belong to the crustacean, with the principal organism group being copepods. Two copepod species, *Calanus finmarchicus* and *C. helgolandicus*, constitute the major components of the northeast Atlantic and North Sea zooplankton in terms of biomass, abundance, and trophic role (Marshall and Orr, 1972). These populations follow distinct spatial and seasonal dynamics such that *C. finmarchicus* is a northern spring species, whereas *C. helgolandicus* is located in

Figure 7 An example of copepod species found in the zooplankton; two *Acartia tonsa* copepods with ingested food item *Thalassiosira weissflogii* (photos courtesy of Kajsa Tönnesson).

warm-temperate waters and reaches its maximum abundance in autumn. The distribution of these species of *Calanus* has been studied during the period 1958–1995 in the North Atlantic (Figures 8–10) in relation to the year-to-year variability in the North Atlantic Oscillation (NAO). The NAO is a climatic oscillation affecting the hydrology and climate in the North Atlantic Ocean and adjacent region, and it can be compared to El Niño in the Pacific Ocean. After 1987, the zooplankton community in the North Sea changed with, for example, an increase in the abundance of the copepod *Corycaeus* spp. and it may have also affected the distribution and abundance of the two *Calanus* species. The increase in temperature, wind, and alteration of the winter circulation pattern observed during years of a high positive NAO index have resulted in unfavorable conditions for the *C. finmarchicus* population leading to a significant decrease in the abundance of the species. Conversely, these hydro-climatic shifts have proved beneficial to *C. helgolandicus*, the abundance of which has increased during these years (Planque and Taylor, 1998; Stephens *et al.*, 1998).

In the northeast Pacific the plankton community structure (Figure 11) responded to the warming in 1958 to 1960 in the California Current in relation to an El Niño event that caused a sudden change in the SST distribution (McGowan *et al.*, 1998). The zooplankton abundance has generally decreased in the California Current system while, in a synchronous manner, the zooplankton abundance in the Gulf of Alaska gyre increased. These interdecadal regime shifts in these two systems driven by

Figure 8 The mean spatial distribution of the abundance of two species of calanoid copepod *Calanus finmarchicus* and *Calanus helgolandicus* in the northeast Atlantic and the North Sea, in relation to years of both low and high NAO. The color scale is proportional to the log abundances of the species. High NAO years, 1983 and 1989–1992; low NAO years, 1963, 1964, 1966, 1977, and 1979 (maps from Planque, 1997, courtesy of SAHFOS).

Figure 9 Regional distribution of *Calanus finmarchicus* and *Calanus helgolandicus* for the years 1958–1992 (maps from Planque, 1997, courtesy of SAHFOS).

climatic variations in the atmosphere are reflected first in changes in the physical structure of the ocean resulting in large-scale biological responses in the ocean. These regime shifts have a severe effect on the temporal and spatial distribution of planktonic species, leading to changes in the secondary production as well as in community structure (McGowan *et al.*, 1998). In terms of species richness and diversity in the open area of the Atlantic Ocean, the maximum species richness is found at depths between approximately 1000 and 1500 m. Angel (1991) showed, for example, that the species richness of planktonic ostracods in the northeastern Atlantic at 20° W occurred between 500 and 1000 m. Moving up the water column, and at higher latitudes, there tend to be fewer species but these occur at higher abundances. The zooplankton, and especially the *Calanus* species, are an important part of the pelagic food web since they are the major source of food for fish species including cod. The nauplii of *Calanus* in particular are a key component of the diet of fish larvae and a recent model of *Calanus* off the Georges Bank (Miller *et al.*, 1998) showed clearly the importance of the availability of *C. finmarchicus* for the cod and haddock populations along the bank (Lough, 1984).

Recent evidence shows that SST explains almost 90% of the geographic variation in planktonic foraminiferal diversity for the whole Atlantic Ocean (Rutherford *et al.*, 1999). The peak in foraminiferal diversity was found at middle latitudes in the Atlantic, and this pattern may be extended to other taxa such as euphausiids (krill species), pteropods, and chaetognaths in the North Pacific. This is additional evidence that changes in pelagic

Regional variations in the seasonal cycle of *C. finmarchicus*

Figure 10 Regional variation in the seasonal cycle of *Calanus finmarchicus* showing how the distribution varies in the North Atlantic and how the peak of the log abundance differs between different locations (maps from Planque, 1997, courtesy of SAHFOS).

diversity in the world's ocean result from changes in the upper-ocean physical structure and especially that water column and ecosystem structure may depend on vertical niche separation.

In the North Sea, particularly the northern areas, there has been an increase in zooplanktonic species richness, as recorded by the CPR survey, since the 1950s. The increase, particularly of calanoid copepods, in the most northerly areas can be attributed to increased inflow from the Atlantic Ocean, but currently the species which are increasing or adding to the numbers are not permanent components of the North Sea plankton. Resident and colder water holoplanktonic species have declined in abundance, and meroplankton (adult and larval) and expatriates from warmer oceanic and mixed waters have increased. This constitutes a significant challenge to analysis of pelagic diversity because the species richness of the meroplanktonic groups may exceed that of the holoplanktonic groups. For example, in a region of the northwest North Sea, 17 calanoid copepod species were recorded in 10 years of CPR samples, but 24 species of decapod larvae were recorded in 2 years and 34 species of bivalve larvae in just 1 year. Meroplankton species, larval and adult, are linked to the more permanent habitats of the benthic phases of their life cycle, whereas holoplankton live entirely within a dynamic water mass, complicating the description of plankton diversity at a specific geographical location.

Pelagic Fish

In the marine environment, approximately 80% of the known fish species are found in coastal areas, whereas approximately

Figure 11 An example of changes in a pelagic food web in relation to a large El Niño event in California, (a) Correlations of abundance for zooplankton taxa between the years 1955 and 1959. (b) Similarities found using rank-order abundance of plankton. The years 1955–1957 showed no correlation with years 1958 and 1959. Note that 0.05, 0.01, 0.001 and the respective thickness of the line indicate the significance level of the correlations (redrawn from McGowan *et al.*, 1998).

2% are epipelagic and the remaining are deep-sea species. For example, at a 1000-m depth in the North Atlantic 44° N 13° W, the fish were the most taxonomically diverse group found in the micronekton (Angel, 1993). In the pelagic food web, pelagic planktivorous fish are regarded as predator species and changes in their prey items in relation to physical changes in the ocean circulation pattern are reflected in fish stock fluctuations (Figure 12) and changes in the catches of one species of sardine, *Sardinops sagax* (Kawasaki, 1991; Sharp and McLain, 1993; Strömberg, 1997). The increase in the sardine populations may reflect changes in phytoplankton biomass in the Pacific Ocean during the 1970s and 1980s (Venrick *et al.*, 1987) as well as changes in zooplankton abundances in the northeast Pacific. Zooplankton populations off the Peruvian coast declined from 1972 coincident with the severe decline in the anchoveta fishery. Shifts in the Kuroshio current southeast of Japan, and shifts in the wind stress, may be related to the fluctuations in sardine populations. The effects of El Niño Southern Oscillation events on the fluctuations observed in the fish stocks are unclear as, for example,

in the case of the Chilean sardine and the Peruvian anchovetta that do not indicate a clear connection. During the El Niño events in the late 1950s, 1960s, and early 1970s, the Peruvian anchovetta stock was high, whereas the Chilean sardine stock was low. In 1971 and 1972, the El Niño event decreased dramatically and as a result the Chilean sardine stock increased while the Peruvian anchovetta stock crashed. At the same time, both the Japanese sardine and the Californian sardine increased. This trend was confirmed during the El Niño events that took place in 1982 and 1983. In the Black Sea the introduction of a new species, the comb jellyfish *Mnemiopsis leidyi*, caused a strong decline in the Black Sea anchovy stock. As the abundance of the jellyfish increased, it had a great impact on the recruitment of the anchovy due to changes in the food web and competition for food. These population collapses are very important since pelagic fish such as sardine and anchovy species are among the top 10 species that dominate the world catches.

If we examine the long-term studies of plankton in the North Atlantic observed by the CPR, we find that in the North

Figure 12 The covariation of three different populations of Pacific sardine compared with the temperature anomaly from the North Pacific in relation to ENSO events. The data for the California sardine are part of the California Cooperative Fisheries Investigations (CALCOFI) (data from Kawasaki T (1991) Long-term variability in the pelagic fish populations. In: Kawasaki T, Tanaka S, Toba Y, and Taniguchi A (eds.) *Long-Term Variability of Pelagic Fish Population and Their Environment*. New York: Pergamon, and Sharp GD and McLain DR (1993) Fisheries, El Niño-Southern Oscillation and upper-ocean temperature records: An eastern Pacific example. *Oceanography* 6:13–22; redrawn from Strömberg J-O (1997) Human influence or natural perturbation in oceanic and coastal waters—Can we distinguish between them? *Hydrobiologia* 352: 181–193).

Sea after 1987 an increase in phytoplankton biomass coincided with taxonomic changes in the phytoplankton and zooplankton species and a large increase in the catches of the western stock of the horse mackerel *Trachurus trachurus* L. in the northern North Sea. This reflected a northerly expansion of the stocks along the shelf edge from the Bay of Biscay to the North Sea after 1987. The increase in the western horse mackerel may be related to the fact that this species tracked down an increase in food resources available in the North Sea during high NAO years. The presence after 1988 of an unusual plankton species (for the North Sea), *Eucheta hebes*, which normally has a more southerly/oceanic distribution, suggests an increase in the shelf edge current that in turn favored the advection of western horse mackerel from the western margin of Europe, allowing them to reach the northern North Sea. As noted by Strömberg (1997), the causes and events related to the fluctuations in the standing stocks of pelagic fish in relation to changes in the plankton and to production are very complex, and these changes may be related to wind-driven advection processes and to a change in the behavior of predator and prey in response to changes in the small

turbulent flow. In the coastal areas, and in particular in the shelf seas, very abrupt changes in the community structure can occur and persist on a decadal scale (Steele, 1998). The observed changes in the dynamics of pelagic fish stocks may be related to low- and high-frequency climatic variability that in turn affects the interannual variation in recruitment, growth, and abundance. For example, in a time series analysis of variation in O-group cod *Gadus morhua* along the Norwegian Skagerrak coast, variation was found to not be directly associated with the NAO and with the abundances of *C. finmarchicus*, but the fluctuations in the cod stock may have been related to changes in the bottom habitat and especially in the seagrass coverage by *Zostera marina* (Fromentin *et al.*, 1998). Further analysis of this data set demonstrated the importance of age-structured interactions such as asymmetric competition and cannibalism between cohorts, causing fluctuations in the abundance of the O-group and 1-group juvenile cohorts of cod (Bjørnstad *et al.*, 1999).

The northern stock of cod on the Labrador Shelf and Grand Banks of the northwest Atlantic declined and, although overfishing occurred, other factors also affected stock recruitment. The match/mismatch hypothesis was revisited by Conover *et al.* (1995). This hypothesis basically states that the spawning of cod occurs at the same time each year and if the spawning of copepods (the major food source) occurs at the same time there is a “match” and a successful recruitment. If the spawning of copepods is delayed through dependence on the occurrence of the phytoplankton spring bloom there is a “mismatch” and the recruitment of cod larvae will be low. Changes in the physical structure in the Labrador Sea and Grand Banks occurred with unusually low temperatures in the Labrador current and this was followed by the appearance in the zooplankton of the copepod *Calanus glacialis* rather than *C. finmarchicus*. *Calanus glacialis* spawns later than *C. finmarchicus* and therefore does not provide a good food source for the cod larvae. Changes in the Labrador current may be the result of climate change and in turn this affects the structure of the pelagic food web by creating a shift in the species composition as just described, thus resulting in a change in cod recruitment. Ultimately, the increase in fishing activities may have a severe effect on fish populations (Strömberg, 1997) since indirect effects considerably alter the biogenic habitat for fish recruitment, as does the removal of top predators. These indirect interactions by the fisheries can cause a trophic change in the food web as a result of top-down control of community structure, whereas a change in the resource availability induced, for example, by the El Niño event represents a bottom-up process that influences the dynamics of pelagic ecosystems. The interplay between these two types of perturbation may be the cause of shifts in species composition which result in changes in the food web structure. In light of these processes, we should also consider the importance of the microbial loop (Azam, 1998) and be aware of bacterial control of the fluxes of organic matter and its role in ecosystem dynamics. For example, fish production in the eastern Mediterranean decreased through a dominant microbial loop, and the uncoupling of bacteria from primary productivity was found in a fishery off the coastal region of Newfoundland that was causally related to the intensity of the fishery.

Outlook

The structure of pelagic ecosystems varies at both temporal and spatial scales. At an ocean basin spatial scale, phenomena such as El Niño can be linked at a temporal scale of approximately 1 year to the stock recruitment of pelagic fish, and species and single species models can be used as predictive tools. At a larger spatial scale and on a decadal timescale, climatic oscillations such as the NAO can be linked to regime shifts in the species composition and community structure of ecosystems, and models should be at a community or ecosystem level. A retrospective analysis of historical data could reveal important biodiversity patterns.

The Russell cycle (Russell *et al.*, 1973) explained the changes in the biota of the English Channel very well. In 1925, a decline in the herring stock was observed and the Plymouth herring stock (on the southwest coast of the United Kingdom) collapsed in 1936. In 1931, the decline in the macroplankton resulted in a change in the presence of the arrowworm from the species *Sagitta elegans* to *S. setosa*. In the following decade, there was a drastic decrease in the standing stocks of gadoid fish such as cod (*G. morhua*). The English Channel ecosystem essentially shifted from one dominated by herring and that had a good supply of dissolved nutrients to one with less nutrients and that was dominated by pilchards and smaller planktonic organisms. It is interesting that in 1965 there was an increase in the fish larvae concomitant with an increase in nutrient supply. These events were followed in the 1970s by a reverse switch in the *Sagitta* species and an increase in copepod abundance, whereas the number of pilchard eggs decreased. The Russell cycle is a well-documented example that shows how ecosystems can shift or oscillate from one state to another after reaching a bifurcation point (May and Oster, 1976).

Pelagic ecosystems seem to show decadal or longer oscillations and this is reflected in the fossil records and paleo-oceanographic studies. Pelagic ecosystem diversity and the maintenance of biodiversity appear to be influenced by climatic oscillations and through pressure exerted by overfishing and removal of top predators from the food web (Casini *et al.*, 2009). These can be regarded as macroscopic system properties that in turn are related to different flux that may have an effect on the structure and ecosystem functioning (Levin, 1998). An understanding of changes in biodiversity patterns in relation to the variability in ecosystem structure and function needs to be incorporated in a sustainable global ecosystem policy for the next millennium.

Rainforest Ecosystems, Animal Diversity

Gregory H Adler, University of Wisconsin at Oshkosh, Oshkosh, WI, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Allopatric speciation The evolutionary development of new species in the presence of a geographical barrier which reduces gene flow and promotes genetic divergence.

Neotropics A biogeographic region that includes the New World tropics, extending from southern Mexico through the Southern Cone of South America to Tierra del Fuego. Many different ecosystems are found here, including tropical rainforest.

Species diversity This has two connotations. In a broad sense, it simply refers to the number of species of a particular

taxonomic group living within a given area and is used synonymously with species richness. In a narrow sense, it refers to the number of species within a given area while simultaneously taking into account their relative abundances. In this article, species diversity is used in a broad sense and is used interchangeably with species richness.

Species richness The number of species of a particular taxonomic group living within a given area.

Tropical rainforest A forest that occurs below 1000 m in elevation, experiences high, relatively constant temperatures, and receives at least 200 mm of rainfall per year.

Introduction

Tropical rainforests contain more species of animals than any other ecosystem on Earth. This article reviews the distributions and types of rainforests and the diversity of selected groups of animals in tropical rainforests. The article concludes with a discussion of the global and regional patterns of rainforest animal diversity, some hypotheses that have been developed to explain the high diversity, and the future of rainforest animal diversity.

It is indeed ironic that Linnaeus, cataloging specimens collected by early naturalists for the museums of Europe, considered the tropics to be of low diversity. However, the first naturalists collected solely in villages that contained second-growth vegetation and where hunting was intense. It was not until naturalists penetrated the dense border of vegetation between villages and undisturbed forest that the high diversity became evident. Single collecting expeditions routinely returned to Europe with thousands of undescribed species of plants and animals. Discoveries of new species of animals continue into the twenty-first century. It has been estimated that several million species of insects alone are yet to be discovered from tropical rainforests. Even larger and presumably more conspicuous animals, such as birds and mammals, are being discovered every year in the world's tropical rainforests. For instance, in the 1990s new species of monkeys were found in Brazil and two new species of deer and a relative of the goat were discovered in Laos and Vietnam. New locality records are also being established for many species of animals. For instance, the Andean spectacled bear has recently been found in

lowland rainforests, although it has long been considered to occupy only higher elevation cloud forests. Alston's mouse opossum, formerly known only from parts of Central America to western-most Panama and again in western Colombia, recently has been found in lowland rainforest in central Panama.

Definition and Geographical Context

Tropical forests cover much of the land area that lies between the Tropics of Cancer and Capricorn (23°30' N and S latitude). Tropical forests also extend outside of the two tropics in southeastern Brazil and northeastern Australia. The lowland tropics have a relatively high constant temperature, where the mean temperature of the coldest month is at least 18 °C. However, not all warm areas in the tropics support tropical forest. Rainfall, in concert with high stable temperature, is a crucial factor determining the development of forest. In many areas, closed-canopy forest begins to develop where there is at least 800–1000 mm of rain per year (Mabberly, 1992; Kricher, 1997; Whitmore, 1998; Leigh, 1999). Although the term rainforest has been applied loosely and sometimes inappropriately to virtually any type of tropical forest, a more precise definition of rainforest has been developed. Tropical rainforests occur in areas of high, relatively constant temperature (below approximately 1000 m in elevation) and where rainfall exceeds 2000 mm per year. A dry season may occur but generally does not exceed 4 months in duration. Forests growing under such conditions are composed

primarily of evergreen trees (< 15% of the trees are deciduous) and have a closed canopy of at least 25 m in height. Larger trees, called emergents, often protrude above the canopy and may reach heights of up to 50 m. Thus, rainforests are defined based on the temperature and precipitation regimes under which tropical forests develop and also on the structural characteristics of these forests.

An understanding of the geographical context of rainforests is necessary to a discussion of animal diversity in these forests. For historical reasons (i.e., evolutionary origins of taxa in specific geographical regions and subsequent inability to disperse to other regions), many groups of animals are geographically restricted to single tropical regions. Vertebrates illustrate this point. The species-rich frog family Leptodactylidae is restricted to the New World and reaches its greatest diversity in rainforests. Iguanas (Iguanidae) and anoles (Polychrotidae), two species-rich families of lizards with greatest diversity in rainforests, are restricted to the New World, except for iguanas in Fiji that stem from New World colonizers. Families of birds such as toucans (Ramphastidae), motmots (Motacidae), jacamars (Galbulidae), puffbirds (Bucconidae), wood-creepers (Dendrocolaptidae), ovenbirds (Furnariidae), antbirds (Thamnophilidae), anthrushes (Formicariidae), and cotingas (Cotingidae) are restricted to the New World tropics, with many species occurring in rainforests. Birds such as hornbills (Bucerotidae), honeyguides (Indicatoridae), broadbills (Eurylaimidae), sunbirds (Nectariniidae), white-eyes (Zosteropidae), and pittas (Pittidae) are restricted largely to the tropics of the Old World (with a few species found also in adjacent subtropical regions). Birds of paradise (Paradisaeidae) and bowerbirds (Ptilonorhynchidae) are restricted to the tropics of Australia and New Guinea. Marsupials, which reach their greatest diversity in rainforests and surrounding areas, are restricted to the New World and the Australopapuan region. Among primates, two families of monkeys (Callitrichidae and Cebidae) are restricted to the New World tropics, whereas Cercopithecidae is restricted to the Old World and Hylobatidae is restricted to Southeast Asia. The lemurs, a group of primates composed of five families, are found solely in Madagascar.

Rainforests are found in three major regions of the world (Mabberly, 1992; Whitmore, 1998). The rainforests of the neotropics cover the greatest area (approximately 4 million km²) and extend from southern Mexico to southeastern Brazil. The neotropics contain four fairly distinct regions that are isolated from each other by mountain ranges, savannas, or scrub vegetation. Trans-Andean rainforests are distributed from Chiapas and Veracruz, Mexico, to the Pacific slope of Colombia and Ecuador. Venezuelan coastal rainforests are found in northern Colombia, Venezuela, and the Guianas. Amazonian rainforests occupy most of the Amazon basin and constitute the largest contiguous area of tropical rainforest in the world. Atlantic rainforests formerly covered a long narrow swath of coastal southeastern Brazil but have been reduced to remnant patches by human activity. Only about 10% of the Atlantic rainforest remains. The Asia-Pacific tropics, also known as Malesia, extend from China's Yunnan Province southward to Australia. Included in this region are large parts of Southeast Asia (Burma, Thailand, Malaysia, Indonesia, Singapore, Cambodia, Laos, and Vietnam) and the Australopapuan region (New Guinea, northeastern Australia, and tropical Pacific islands such as New Caledonia,

the Bismarck Archipelago, Solomon Islands, Fiji, and Vanuatu). Asia-Pacific tropical rainforest also occurs far to the west in the Western Ghats of India. This discontinuous and largely insular block of rainforest is second in areal extent only to the neotropics, covering approximately 2.5 million km². The Australopapuan region harbors faunal elements that are sufficiently distinct to sometimes warrant separate treatment. For instance, monotremes (egg-laying mammals), marsupials, and several families of birds are found there but not in the remainder of the Asia-Pacific tropics. Conversely, many families of birds and mammals are not found in the Australopapuan region but occur in the remainder of the Asia-Pacific tropics. Africa contains a large block of rainforest in the Congo River basin in central Africa and a smaller block of rainforest in West Africa. An outlying area of rainforest occurs in eastern Madagascar. The African rainforests cover approximately 1.8 million km².

Types of Rainforests

Researchers frequently delimit lowland tropical forests based on annual amounts of rainfall such forests receive and the temporal distribution of rainfall. These delimitations are somewhat arbitrary, and it is important to recognize that contiguous forest often occurs along a rainfall gradient where one type of forest grades into another with little obvious demarcation. Tropical scrub forest and tropical dry forest typically receive less than 2000 mm of rain per year, most of which falls in a few months. Severe dry seasons of up to 8 or 10 months punctuate the short rainy seasons, and many trees are deciduous and shed their leaves during the dry season to conserve water. Such forests, particularly scrub forests, often do not have a closed canopy. If the authors adhere to their definition of rainforests given previously, then these tropical forests do not constitute true rainforests (although they frequently abut rainforests and share many species of animals), and this article will not discuss their animal diversity. The remaining forest types that will be discussed are sometimes referred to as semievergreen and evergreen forests and conform to the definition of tropical rainforests. Tropical moist forests receive from about 2000 to 4000 mm of rain per year. These forests frequently have a pronounced dry season of up to 4 months, but heavy rains may occur during the dry season. Deciduous trees may occur in such forests, but they are much less frequent than in the preceding two types of forests. Tropical moist forests occupy the greatest areal extent of rainforests and occur throughout much of the three major geographical rainforest regions. Tropical wet forests typically receive more than 4000 mm of rain per year and frequently have no extended dry season. The wettest of these forests (those forests receiving more than 8000 mm of rain per year) sometimes are designated as pluvial forests and are essentially a seasonal. The driest months in these forests typically receive more rain than the wettest months in tropical moist forests.

Tropical forests may also be defined based on the elevations at which they occur. In mountainous areas, contiguous forest may be found from near sea level to the tree line. However, forest characteristics change dramatically with elevation. The upper elevational limit of lowland rainforests is frequently considered to be 1000 m, where premontane forest often occurs,

although this limit is arbitrarily chosen. Lower montane and upper montane forests, which do not fall within the operational definition of lowland rainforests, occur at increasingly higher elevations. In some areas, montane forests may occur at elevations lower than 1000 m, depending on latitude and stature of mountain ranges. For instance, small mountain ranges and lower spurs from larger ranges often support montane forests at lower elevations, which is termed the Massenerhebung effect. This article will focus on animal diversity in lowland rainforests (i.e., tropical moist and wet forests lower than 1000 m).

Overview of Animal Diversity

Tropical-temperate comparisons of diversity are commonly made to highlight the high diversity of the tropics, and this latitudinal diversity gradient has attracted considerable attention from ecologists and evolutionary biologists. These comparisons show that many major groups of animals reach their greatest diversity in tropical rainforests. Conspicuous among groups of animals that reach their greatest diversity in such forests are beetles, butterflies, frogs, birds, and mammals. This article will focus on these groups because they best exemplify the diversity of rainforest animals, and tropical-temperate comparisons will be included to highlight rainforest diversity.

It should be noted, however, that other major groups of animals, particularly among invertebrates, have been poorly sampled in tropical rainforests. It is evident, however, that other such groups also exhibit high rainforest diversity. For example, 498 species of spiders in 33 families were collected during 6 weeks at Pakitza in Manu National Park, Peru. Many of these specimens represented new species. Several weeks of sampling at the same site yielded 224 species of caddisflies (order Trichoptera), 66% of which could not be identified confidently. Sampling of dragonflies and damselflies (order Odonata) in the same area yielded 117 lowland rainforest species. At Tambopata Reserve in Peru, 135 species of ants were found, and one individual tree harbored 43 species, which is approximately the total number of ant species found in the entire British Isles or in all of Canada. The 1500-ha La Selva reserve in Costa Rica contains an estimated 4000 species of moths. Thus, when invertebrates have been sampled in tropical rainforests, diversity is usually very high, and new species invariably are found.

Diversity of Beetles

Approximately 1.4 million species of organisms have been described, about 400,000 of which are beetles. Beetles therefore constitute greater than one-fourth of all living species that have been cataloged by taxonomists. Beetles have been poorly sampled in rainforests, and any discussion of their diversity will be incomplete. However, it is clear from even preliminary sampling that beetle diversity is extremely high and that beetles no doubt are the most species-rich group of rainforest animals, comprising an estimated 40% of all arthropods. Indeed, the majority of rainforest animal species may be still the undescribed beetles.

There has been considerable conjecture over how many species of beetles occur in rainforests. Rainforest beetles reach their greatest richness in the canopy, in which standardized

sampling efforts have been concentrated. Such sampling involves the deployment of insecticidal sprays into the canopy, a process known among "coleopterists" (scientists who study beetles) as fogging. Sampling of beetles (excluding weevils) by fogging 19 individuals of a single species of rainforest tree (*Luehea seemanni*) in Panama produced 955 species, 163 species of which were found only on this one species of tree. This preliminary sampling was used to estimate the total number of arthropod species in tropical rainforests (Erwin, 1982). The estimate was based on the number of beetle species restricted to a single species of tree, the approximate number of tropical tree species, the proportion of arthropods that are beetles, and the contribution of canopy species to the overall arthropod species pool. Based on this reasoning, estimates of 30–50 million species of insects and >7 million species of beetles have been derived, which indicate that insects may constitute about 97% of all species of living organisms on Earth and that tropical rainforest beetles contribute the greatest proportion of species. These estimates of global biodiversity based on rainforest beetles stimulated biologists to reassess their more traditional estimates of global biodiversity (Wilson and Sandoval, 1996).

Sampling of ground beetles (Carabidae) at Pakitza in Manu National Park, Peru (not all species of which are confined to the ground), has revealed this 4000-ha site to have the greatest species richness of this family ever recorded. Indeed, nearly as many species have been found in this small area as have been found in all of New Guinea. More than 600 species have been recorded from Pakitza, and not only many new species but also new genera have been discovered. It should be noted that sampling was incomplete and that dozens of additional species are expected.

Comparison of beetle species richness among sites is difficult because of differences in sampling methodology and intensity and the paucity of sufficiently rigorous studies. However, several studies using the standardized fogging methodology allow researchers to calculate species richness on equal footing as the number of species per m³/m. Among canopy and subcanopy beetles, estimates range from 0.02 species per m³m⁻¹ in an Australian rainforest tree and in rainforest in Sulawesi to 1.5 species per m³m⁻¹ in a Peruvian rainforest. Other estimates for rainforest sites are 0.29 species per m³m⁻¹ in New Guinea, 0.32 species per m³m⁻¹ in Brunei, and 1.17 species per m³m⁻¹ in Panama. The estimate for Panama was derived from the same data set from which global biodiversity estimates were made.

Diversity of Butterflies

Unlike most groups of insects, butterflies have been studied so extensively that about 90% of all living species presumably have been described. An estimated 13,750 species of butterflies, excluding skippers (family Hesperiidae), occur in the world. With skippers included, the number is approximately 17,500 species. Because of our thorough understanding of butterfly systematics, they are perhaps the most appropriate insects for examining rainforest diversity.

A tropical-temperate comparison of butterfly diversity highlights the great richness of tropical rainforest butterflies.

Table 1 Approximate numbers of butterfly species in four families in lowland rainforests of Costa Rica compared with lowland temperate forests of West Virginia

Family	West Virginia	Costa Rica
Papilionidae	5	25
Pieridae	4	31
Riodinidae	1	208
Nymphalidae	16	234
Total	26	498

Table 1 shows the numbers of butterfly species in four families in temperate forests of West Virginia and tropical rainforests of Costa Rica. These two areas are of comparable size, and the butterfly faunas in the four families are well-known (De Vries, 1987, 1997). Butterflies in two additional families (Lycaenidae and Hesperiidae) are too poorly known to make a valid comparison with those in West Virginia. Included in the species tally for West Virginia are those species known to occur in all forest types below 1000 m, whereas the species tally for Costa Rica includes only those species that are known to occur in lowland rainforests. Thus, butterflies occurring in both dry and wet temperate deciduous forests are included in the tally for West Virginia, but habitats such as tropical scrub and dry forests and mangrove forests are excluded from the tally for Costa Rica.

It is important to note that species tallies will likely vary depending on definitions of forest types and the compilation of results from additional sampling and natural history studies. Many species of butterflies live in disturbed areas adjacent to rainforest but are not included in the species tally because they are not true denizens of the rainforest.

Regardless of such qualifications, it is clear that rainforest butterfly diversity is much higher than in temperate forests. Costa Rican rainforests harbor nearly 20 times as many species of butterflies in the four families. Of particular note is the extremely high relative diversity in two Costa Rican families, Riodinidae and Nymphalidae, which together constitute nearly 90% of Costa Rica's rainforest butterfly fauna (De Vries 1987, 1997). Although the majority of West Virginia forest species are nymphalids, only one species of riodinid is found in West Virginia's lowland forests, and the two families together constitute only 65% of the total butterfly fauna.

Sampling at single sites further reveals the high species richness of Costa Rica's butterfly fauna. At the 1500-ha La Selva reserve in Costa Rica, 204 species have been recorded. However, Costa Rica's rainforest butterfly fauna is not particularly rich relative to that of other rainforest sites, especially in the neotropics. On a nineteenth-century expedition to the Amazon, Bates found 550 species of butterflies at a single site. This number is small compared with the total butterfly list for sites in the Peruvian Amazon. Within a 200-ha study site at the Explorer's Inn Reserve in southern Peru, 1234 species have been recorded, and approximately 1300 species have been recorded from Pakitza in Manu National Park. Thus, these single sites contain approximately 10% of all butterfly species in the world. The total numbers of species at these sites and other sites in the neotropics are not final; virtually every collecting expedition to these sites finds additional species. Indeed, the

1300 species from Pakitza were collected during only five sampling trips that averaged <3 weeks in duration. Nonetheless, the butterfly lists for these single sites exceed the lists for virtually all countries in the African and Asia-Pacific tropics.

Diversity of Frogs

Frogs are conspicuously species-rich in tropical rainforests, and their richness is particularly evident when breeding. At a single site in the Amazon rainforest in Santa Cecilia, Ecuador, 81 species of frogs have been recorded, which to date is the highest tally of frog species for any single site in the world. The number of species at this site equals the total number of frog species in the entire United States. High frog species richness has also been recorded from other tropical rainforest sites (Inger, 1980). In Panama, 59 species of frogs have been recorded on the 1500-ha Barro Colorado Island. More than 40 species have been recorded from La Selva, Costa Rica, 38 species from Makokou, Gabon, 25 species from Pasoh, Malaysia, and 23 species from Gogol, Papua New Guinea. On the island of Borneo, 33, 51, and 46 species of frogs have been recorded at three different lowland rainforest sites, respectively, and 29 species of larval frogs have been recorded from rainforest streams at Nanga Tekalit in Sarawak. At Sakaerat, northern Thailand, 19 species of frogs have been recorded within rainforest, with an additional five species found in adjacent dry forest.

Diversity of Birds

Tropical rainforests typically harbor the greatest diversity of birds compared with other ecosystems (Stotz *et al.*, 1996). Costa Rica's bird fauna is well-known, and a comparison of the number of resident bird species in that country's lowland rainforests with resident birds in all forest types in West Virginia illustrates this point. **Table 2** gives the approximate number of bird species that are resident in Costa Rica's lowland rainforests compared with the number that are resident in lowland forests of all types in West Virginia. Excluded from this list are migratory species that breed in West Virginia or that overwinter in Costa Rica. Also excluded are species that are found in disturbed areas adjacent to rainforests, in clearings within rainforests, or along major watercourses that may pass through rainforests. Although the same cautionary note applies to this comparison as it did with butterflies, it is again evident that Costa Rica's resident rainforest avifauna is much more diverse than that of West Virginia's lowland forests.

Costa Rican rainforests contain more than eight times as many species of birds as do all lowland forest types in West Virginia. Much of this greater diversity stems from two taxonomic sources. First, Costa Rican rainforests harbor more families of birds with resident species (42 compared with 18 in West Virginia). There are 29 families of birds that have representatives that are resident in Costa Rican rainforests but not in West Virginia's forests, and these families contribute 218 species to the total rainforest avifauna. By contrast, only seven families have resident species in West Virginia's forests but not in Costa Rican rainforests, and these families contribute only

10 species to West Virginia's resident forest avifauna. Second, several families that have resident representatives in both areas are much more diverse in Costa Rican rainforests. For example, approximately 21 species of hawks are rainforest residents, compared with only four resident forest species in West Virginia; 12 species of pigeons and doves are rainforest residents, but only one species is resident in West Virginia's forests; 44 species of tyrant flycatchers are rainforest residents but only one is a resident in West Virginia (although many species are migratory); and 14 species of wrens are rainforest residents but only two species are resident in West Virginia. This comparison shows that bird diversity is higher not only at the species level but also at higher taxonomic levels and highlights a common theme in tropical-temperate comparisons of diversity: There is often greater representation at higher taxonomic levels such as genus and family in tropical rainforests, and there are generally several higher level groups that are particularly rich in species in rainforests.

High bird species richness is typical of tropical rainforests, and Costa Rica's rainforests may be considered about average with respect to number of species. Approximately 410 species of birds have been found at La Selva in Costa Rica, an area of approximately 1500 ha. However, not all of these species are truly rainforest birds. If only rainforest birds are included (i.e., birds frequenting open water, marshes, cleared areas such as pastures, etc. are excluded), the total list is approximately 338 species. Approximately 314 rainforest species

have been found on Barro Colorado Island and adjacent mainland areas, with a list of all species nearing 400. By contrast, about 554 species of birds have been recorded from Cocha Cashu, Peru, with nearly 400 truly rainforest species. To date, 575 species of birds have been found adjacent to the Explorer's Inn Reserve, an area of 5500 ha in the Amazon rainforest of southern Peru. The majority of these birds are rainforest species.

Other rainforest regions also have high bird diversity. Khao Yai National Park, Thailand, harbors 318 species, approximately 216 of which are true rainforest species. A single plot of <50 ha in southern Vietnam contains 164 species of forest birds. Makokou, Gabon (2000 km²), has 342 species of birds; 212 species have been recorded from Pasoh, Malaysia (800 ha), and 162 species from Gogol, Papua New Guinea (1000 ha). Although not all species recorded from these last three sites are true rainforest residents, the majority can be considered rainforest species.

Diversity of Mammals

Table 3 highlights the high diversity of rainforest mammals by comparing the approximate number of species that are found in Costa Rica's lowland rainforests with that of lowland forests of West Virginia (including species that were extirpated following European colonization). Costa Rican rainforests contain nearly three times as many species of mammals as do forests in West Virginia. A comparison of families shows the same trend with birds. There are 31 families represented in Costa Rica's rainforest mammal fauna and only 17 represented in West Virginia's forests. The 20 families that have rainforest representatives in Costa Rica but not in West Virginia's forests contribute 97 species. By contrast, six families contributing only eight species have lowland forest species in West Virginia but not in Costa Rican forests. Particularly noteworthy are bats (order Chiroptera). Only 11 species of bats, all from a single family, are found in West Virginia's forests, but approximately 89 species of bats in nine families are found in Costa Rican rainforests. A single family, Phyllostomidae, contains 56 rainforest species. However, not all higher level taxonomic groups are more species rich in rainforests. For instance, the order Insectivora contains nine lowland forest species in West Virginia but only two in Costa Rican rainforests. These two species are confined to the upper elevational limits of rainforest in Costa Rica and reach greater richness in montane forests. Similarly, there are 18 species of carnivores in West Virginia forests (four of which have been extirpated from the state) and only 16 in Costa Rican rainforests.

Mammal diversity at single sites within rainforests is concomitantly high (Voss and Emmons, 1996). However, species lists for most sites are certainly low because of inadequate sampling. Within a 3 km radius in lowland rainforest at Paracou, northern French Guiana, 143 species of mammals have been recorded, and more species, particularly bats, are expected. In La Selva, Costa Rica, the mammal list comprises 117 species, with as many as 138 species expected to occur there based on geographical distributions of species that overlap the area but have not been recorded. As with birds,

Costa Rica's rainforest mammal diversity can be considered average. Barro Colorado Island's list comprises 113 species, with as many as 144 species expected. Several study sites located in Amazonian rainforests have species lists of > 130 species, with nearly 200 species expected from these sites. Makokou's list of mammals is 199 species, Pasoh's is 89 species, and Gogol's is 27 species.

By far the most species-rich order of mammals in these rainforests are bats (Chiroptera). Even in well-studied sites, however, bat communities are incompletely known because of difficulties in sampling species such as those that forage above the canopy. New techniques that allow researchers to identify bats based on ultrasonic recordings are adding substantially to bat inventories at sites that have been sampled for decades by more traditional means such as mist netting.

Geographical Patterns of Animal Diversity

Researchers have searched for both global and regional patterns of animal diversity. In particular, researchers have attempted to identify the major rainforest region that harbors the greatest diversity. The answer depends to some extent on the taxonomic group under consideration. At higher taxonomic levels (e.g., class and order), however, it is clear that the neotropics are generally richest in species. As noted for beetle species richness, Peru and Panama have the greatest numbers of recorded species per volume of canopy and subcanopy foliage, with the Asia-Pacific tropics, particularly Australia, having the lowest richness. Among butterflies, the neotropics again exceed other tropical regions with respect to numbers of species. Comparing species lists of countries or regions of approximately comparable size that occur in the tropics and that have substantial rainforest highlights this point. Panama in the neotropics has approximately 1550 species of butterflies, Liberia in the African tropics has about 720 species, and the Malay Peninsula in the Asia-Pacific tropics has 1031 species. Although not all species in these lists are true rainforest species, the trend of higher butterfly species richness in the neotropics is clear.

Among frogs, a similar trend is evident, with the Neotropical rainforests having the highest species richness. The greatest single-site frog species count is in Ecuador, with other Neotropical sites in Peru and Central America having nearly as many species. Sites in the African and Asia-Pacific tropics have considerably lower frog species richness, with the lowest being in insular sites in the Australopapuan region and rainforests of mainland Asia such as Thailand. However, some sites on the island of Borneo have nearly the same levels of frog diversity seen in some parts of the neotropics.

Ornithologists have long referred South America as the bird continent because of its high bird diversity; approximately one-third of all species of birds occur in this continent. Within single rainforest sites, the highest bird diversity clearly occurs in the neotropics of Amazonia in Peru and surrounding countries on the eastern slope of the Andes. Neotropical rainforests are followed by the African and finally the Asia-Pacific rainforests. Lowest rainforest bird diversity on a per site basis is found in the Australopapuan region, particularly on smaller islands.

Panglobal comparisons of mammal diversity provide a somewhat different view. On a per site basis, mammal diversity is comparable in the neotropics and African tropics. However, bats are better represented in the neotropics, whereas primates are considerably more species rich in the African tropics.

On a regional scale (i.e., within one of the three major rainforest regions), researchers have noted substantial variability in species richness. For instance, with respect to butterflies, a belt of high species richness apparently extends across the neotropics from southern Colombia and the border of Peru and Bolivia at the base of the Andes eastward into the Brazilian states of Rondonia and Acre. However, even within this belt of high butterfly diversity lie areas with apparently lower diversity.

Within the Asia-Pacific tropics, lowest diversity of most taxa is found in the Australopapuan region, particularly on smaller and more isolated islands such as New Caledonia and those of the Bismarck Archipelago, Solomon Islands, Fiji, and Vanuatu. Many of these islands, particularly those in Fiji, New Caledonia, and Vanuatu, lack entire groups such as native rodents and amphibians that have been unable to disperse long distances over open ocean. Other taxa such as butterflies, lizards, and birds, although represented, are depauperate because of island isolation and small island area and a subsequent lack of opportunity for substantial allopatric speciation within an island. Only New Guinea, by far the largest island in the region, harbors taxa that have undergone substantial allopatric speciation.

Soils have a major effect on forest characteristics and productivity and consequently on animal diversity. Although soils of tropical rainforests are notoriously poor in nutrients, there is substantial variability. Where soils change abruptly, differences in forest structure and animal species richness are often evident. For example, the most species-rich sites in the world, those at the eastern base of the Andes, are situated on relatively richer soils. In contrast, the soils of the Guyana Shield in northern South America are particularly poor, and faunas are notably depauperate. Similarly, the sandy soils in parts of the Orinoco drainage of Venezuela are also very poor in nutrients, and animal diversity is often lower than that in surrounding areas with more fertile soils.

Hypotheses of High Species Richness

Explaining the high species richness of tropical rainforests has preoccupied ecologists and evolutionary biologists since naturalists first recognized the tropical-to-polar latitudinal richness gradient and began to appreciate such richness. Many hypotheses have been advanced, but it is important to realize that none of these hypotheses has been adequately tested. It is also important to note that the great richness may be due to a combination of factors, and invoking a single-factor explanation ignores the complexities and intricacies of evolutionary and ecological processes and the long history of geological and climatological changes that certainly influenced diversity. Although the high species richness of animal consumers in tropical rainforests no doubt is linked with the high species richness of the plants that function as primary producers, invoking high plant diversity to explain high animal diversity is

largely inadequate because it does not explain the high plant diversity. In other words, the root cause of higher tropical diversity is left unanswered by such circular reasoning.

Researchers have sought explanations that would account for high diversity of all taxa. Several of the more important hypotheses are briefly reviewed here and may be divided into biotic and abiotic hypotheses. Biotic hypotheses emphasize interactions among species to account for high species richness in the tropics relative to temperate and polar regions. Abiotic hypotheses of species richness rely on climatological and geological processes that may promote greater speciation in the tropics. Several hypotheses are specific to terrestrial ecosystems, but latitudinal richness gradients are also evident in freshwater and marine organisms. Ecologists and evolutionary biologists must therefore grapple simultaneously with the phenomena of high species richness in both terrestrial and aquatic systems to develop explanations that will apply to all systems.

The first of the biotic hypotheses is the spatial heterogeneity hypothesis, which states that the tropics are more heterogeneous in space and structurally more complex, thereby providing more niches for animals to exploit and thus a greater number of species. This hypothesis relies on the development of greater vegetational complexity in tropical forests but does not explain adequately how this vegetational complexity arose.

The competition hypothesis states that because of a more benign climate in the tropics, organisms live closer to their respective carrying capacities. Because organisms are closer to the carrying capacity, interspecific competition for limiting resources is more intense, and such competition promotes morphological and ecological divergence and specialization on a narrower range of resources. Specialization then allows more species to coexist, thereby promoting greater diversity. This hypothesis is based on the presumption of a more benign climate, but quantifying how benign a climate is from each organism's perspective is not possible. It is also not possible to measure whether each organism in the tropics lives closer to its respective carrying capacity.

The predation hypothesis is contrary to the competition hypothesis and states that predation and parasitism are more intense in the tropics, which keep organisms below their carrying capacities. Because organisms are kept below their carrying capacities, more resources are available to support a greater number of species. It has not been determined whether or not predation rates are indeed higher in the tropics (at least not for the vast majority of animal species), and again it is not possible to determine whether or not most animals are below their carrying capacities.

The animal pollinators hypothesis states that there is less wind in the tropics, and therefore plants have evolved a greater reliance on animals to pollinate their flowers. This greater reliance promotes a closer relationship with animals and greater specialization to enhance the mutualistic relationship, which therefore promotes diversity. Establishing that there is a greater reliance on animal pollinators because there is less wind in the tropics is not possible, and this hypothesis applies only to terrestrial systems.

The first of the abiotic hypotheses is the ecological time hypothesis, which states that the tropics are older because they

have not been subjected to the devastating effects of glaciation that occurred in north temperate regions and that periodically covered entire ecosystems under the great ice sheets. A corollary of this hypothesis is that tropical forests underwent a series of contractions and expansions with cyclic changes in precipitation as water was tied up in the expanding ice sheets and subsequently was released with global warming and contraction of the ice sheets. As the tropical forests contracted, they became isolated as refugia within a matrix of drier savanna and scrub ecosystems. Isolation into refugia promoted allopatric speciation and greater species richness. This corollary was an attractive explanation for pockets of endemism found in organisms such as birds in Amazonia but has become controversial.

The area hypothesis states that the tropics occupy a greater area and that more species occur there because of the species-area relationship. This hypothesis also states that there are more geographical barriers, such as mountain ranges and large rivers, in the tropics, which isolate populations, thereby reducing gene flow and promoting genetic divergence and allopatric speciation.

The energy hypothesis states that there is greater incident of solar radiation striking the tropics and that this solar radiation is more equitably distributed throughout the year. Primary production is consequently greater, which provides more resources for consumers, and more species can consequently coexist. This hypothesis does not address the origin of the greater diversity of species.

The evolutionary speed hypothesis states that generation times are shorter in the tropics and more mutations occur within a given time period. More mutations give natural selection a greater genetic base on which to operate, and speciation rates are consequently higher, which leads to an accumulation of species. This hypothesis and most of the preceding abiotic hypotheses do not explain how more species can coexist in the tropics and consequently do not explain the maintenance of high species richness in the tropics.

More recently, ecologists have focused on the importance of species-specific enemies (seed predators, herbivores, and pathogens) in promoting high tropical plant species richness. Negative feedback, which is an integral component to explain the importance of such enemies in promoting richness, has recently been demonstrated in both shade-house and field experiments (Mangan *et al.*, 2010). Although this hypothesis is specific to plants, such negative feedback may indeed lie at the root of animal diversity as well because all animals ultimately rely on the primary producers, either directly or indirectly.

The Future of Rainforest Animal Diversity

Much has been written about the rapid rate of tropical rainforest clearance by humans and subsequent impacts on animal diversity. Indeed, virtually every volume that has been written in the past two decades on rainforests addresses the potential for a catastrophic decline in global biodiversity. Several biologists have argued that the earth is on the verge of another mass extinction event of the magnitude of the Cretaceous event that eradicated the dinosaurs. Although such arguments are persuasive, it is not possible to predict

accurately the magnitude of an impending extinction episode, particularly because current knowledge of rainforest biodiversity is very limited and no precise estimate of numbers of species is available. However, with approximately 10% of the earth's entire butterfly fauna and untold thousands of species of other animals found within a single 200-ha tract of tropical rainforest, it is not difficult to surmise that the clearing of large tracts of such rainforests indeed will lead to a major decline in global animal diversity.

Introduction

The tropical rainforests grow in conditions of high rainfall (usually more than 2000 mm per year) with few, if any, dry months, where a month would be considered dry if less than 100 mm of rain fell. The temperatures in the lowlands generally average approximately 27 °C, with little variation throughout the year. The day course of temperature with peaks in the afternoon and lows before dawn is frequently the major signal in long-term records—the so-called tropical diurnal climate. Tropical rainforest will grow under climatic conditions of relatively short dry seasons, or even quite long ones if groundwater is available to the trees. As the length and severity of the seasonal drought increases, the proportion of deciduous species in the canopy of the forest tends to increase. When more than about one-third of the canopy trees are drought-deciduous, the forest is no longer tropical rainforest by many definitions.

The plant species of the lowland tropical rainforest are generally intolerant of freezing and frequently sensitive to chilling temperatures. Many major tropical plant families have few members outside the tropics (e.g., the nutmegs, Myristicaceae), possibly because they have not developed cold tolerance.

The tropical rainforests constitute a belt of evergreen vegetation that until relatively recently almost provided a continuous link across the landmasses near the equator. Only in East Africa is rainforest naturally rare. The largest contiguous areas of rainforest were the basins of two major rivers, the Amazon in South America and the Congo in Africa. These essentially continental rainforests can be contrasted with the largely insular forests of the Asia-Pacific region.

Overview of Tropical Rainforest Biodiversity

Biodiversity can be assessed at many different levels ranging from the genetic diversity within populations to landscape or regional heterogeneity. The scale of assessment most widely studied and best understood (though still poorly known) is that of species diversity, which is the focus of this review. The meaning of the term species remains a contentious issue in biology, but in practice in the tropics species are defined by the judgment of taxonomists based largely on the gross morphology of specimens.

There can be little doubt that tropical rainforests are the most species rich of terrestrial ecosystems. Naturally they would cover about 6% of the earth's land surface. Therefore, the high species diversity is not merely a reflection of the tropical rainforests covering an enormous area. The high diversity, relative inaccessibility, and remoteness from major centers of taxonomic research (mostly situated in Europe and North America) have compounded to slow progress in completing the basic inventory of the vascular plants of the humid

tropics. Most tropical areas are studied by ongoing projects to provide floras, but progress on most of these is very slow. The *Flora of Tropical West Africa* is the only major tropical flora to have been completed. Others, such as *Flora Neotropica* and *Flora Malesiana*, have published accounts for relatively small proportions of the floras they cover despite decades of work. At this pace, it may take centuries to complete the flora production. However, the state of affairs may not be as bad as it seems because much information is available in monographs, local floras, and checklists. Nevertheless, some tropical areas, notably Central Amazonia, are still poorly known and estimates of plant diversity in terms of named species must be considered as provisional and tentative. Of extant living organisms, vascular plants are among the most completely described, but there remain many undescribed taxa. Exactly how many species remain unnamed cannot be estimated readily, but I suspect that the floristic inventory of the tropical forests has reached a stage at which the number of recognized species will change relatively little because descriptions of new species are heavily compensated for by synonymization among over-described taxa.

In Table 1, I have attempted to estimate the total plant diversity (in terms of species richness) of the tropical rainforest regions of the world. It is difficult to assess the accuracy of this estimate, and until a species list is compiled it will remain uncertain. However, the derived data provide some interesting results. First, the vascular plant species richness of the tropical rainforests amounts to more than half of the estimated global total of 240,000. This clearly indicates the important contribution of tropical rainforests to global biodiversity. Second, on the broad geographic scale the data allow comparison of the three main rainforest blocks: the neotropics, tropical Africa (including Madagascar), and the Far Eastern tropics from India into the Pacific. Africa evidently has far fewer species than the other two areas, and the neotropics are the most diverse. To a first approximation, a 3 : 2 : 1 ratio of species richness between tropical America, tropical Asia-Pacific, and tropical Africa can be considered, with an approximately equal proportion of diversity between the Old and New Worlds. At higher taxonomic levels the Neotropical dominance tends to disappear. For instance, it has been estimated that 292 higher plant families are represented in the neotropics, but Malesia, with fewer than half the number of species, has 310 families in its flora (Prance, 1994). Southern Indo-China is the region of the world most diverse in angiosperm families (Williams *et al.*, 1994).

The Rainforest Community

Any visitor to a tropical rainforest can readily appreciate the botanical diversity they contain because of the many forms of

Table 1 Estimates of the number of vascular plant species in the tropical rainforests of the world^a

Area	No. of species	Notes
Neotropics	93,500	This includes some areas of vegetation other than tropical rainforest, but these are less species rich than the predominant tropical rainforest, so the overestimate is not too large.
African tropics	20,000	
Mainland Africa	16,000	Guineo-Congolian and Afrotropical phytocoria totals combined. The overlap in species may be compensated by the failure to include species from the small rainforest areas of East Africa.
Madagascar	4,000	Assuming 5000 of the approximately 9500 species are from the island's tropical rainforest and that 80% are endemic (i.e., no overlap with mainland Africa).
Asia-Pacific tropics	61,700	
Malesia	45,000	I suspect this to be an overestimate, but New Guinea is still poorly known botanically and recent studies indicate high levels of diversity and endemism.
Indo-China and adjacent areas	10,000	This is an educated guess on my part. There have been few attempts to consider the flora of this region as a single entity.
Southern India	4,000	Largely the flora of the Western Ghats rainforests.
Sri Lanka	1,000	The endemic rainforest element.
Australia	700	The endemics of the Queensland rainforests that are largely Malesian floristically
Pacific Islands	1,000	There is true rainforest on some of the Pacific Islands but because of their isolation they are relatively poor in species.
Total	175,200	

^aData mostly from WWF/IUCN (1994–1997) and Johns (1995), with permission from IUCN.

plants to be observed ranging from tiny herbs to gigantic trees. There have been numerous attempts to classify plant species by their life-forms. Although there is no universally accepted or universally applicable system, most of these classifications use a similar set of criteria for determining groups within the structure. This set, at its simplest, generally includes plant mature stature and degree of woodiness, need for mechanical support from other plants, and information on trophic requirements. A classification of plant life-forms found in the tropical rainforest, based on these criteria, is given in [Table 2](#).

An area of lowland forest in Brazil would have relatively few plant species in common with a site in Costa Rica and very few indeed in common with sites in Congo or Indonesia, but all would be classified as lowland tropical rainforest. Despite this strong geographic dissimilarity in species composition, there are floristic affinities throughout the world. These occur at higher taxonomic levels, particularly at the rank of family,

but also include some strong generic similarities in makeup. Tropical floras tend to be more similar to each other, in terms of species abundance in common families, than to subtropical and temperate floras (Turner, 1997). [Table 3](#) summarizes floristic data by life-form and geographic area. Gentry (1988, 1993), in particular, emphasized the consistent patterns of family abundances, in terms of numbers of species represented in inventories of forest areas, across the tropics. Among woody stems, families such as Leguminosae, Rubiaceae, Euphorbiaceae, and Myristicaceae are nearly always among the most speciose at a lowland tropical rainforest site. Pteridophytes,¹ Araceae, and Zingiberaceae are frequently the most common ground herbs, and Orchidaceae and Pteridophytes almost invariably dominate the epiphytes. [Table 3](#) lists 17 very large pantropical genera that are well represented in all regions, again emphasizing the floristic similarity of diverse tropical areas. However, there are also differences between regions.

The “dipterocarp substitution” has been noted as a major anomaly in the Asia-Pacific region (Gentry, 1988). That is, in this region the Dipterocarpaceae substitute for Leguminosae as the dominant woody family. The Dipterocarpaceae are a pantropical family, but the vast majority of its species occur in the region from India east to Wallace’s line. In this area, dipterocarps form a majority of the large trees in lowland forests. However, this does not translate into dominance in terms of species abundance in the complete flora, or even the tree flora, unless a very large stem diameter limit is chosen. Legumes are not as numerically important as in American or African floras, but nevertheless they are still well represented, so the dipterocarp substitution is not as important a phenomenon as might be thought. Additionally, East Malesian rainforests have only a small representation of Dipterocarpaceae. [Table 3](#) indicates other regional variations in representation of more important families. Perhaps the most notable of which are the virtual restriction of the important ground herb and epiphyte family Bromeliaceae to the neotropics; the importance of Bignoniaceae and Sapindaceae as climbers in the same region; the paucity of palms, particularly understory species, in Mainland Africa (although not Madagascar); and the abundance of Dichapetalaceae. There are many other smaller families with restricted ranges in the tropics.

Because of the range of spatial scales that can be considered and the relative inclusivity of the sampling, many approaches are available for assessing plant species richness of tropical forests. These include plot, transect, and plotless sampling at small spatial scales that may include all plant taxa present, larger plot sampling that considers only trees and climbers exceeding a certain lower stem diameter limit, and local or regional floristic accounts based on intensive collection within the area concerned. Relatively few efforts have been made to identify all the individual plants present within an area of rainforest largely because few people possess the botanical expertise to identify the enormous amount of juvenile and sterile plant material that such total inventories generate. Recently, an attempt was made to enumerate all the plant species occurring in 1 ha of forest in lowland Amazonian Ecuador.

¹Pteridophyta are frequently accorded “family status” in these analyses.

Table 2 Classification of vascular plant life-forms in the tropical rainforest and a summary of their taxonomic composition

Life-form group	Definition	Examples from tropical rainforest	Subdivisions of the group
Trees	Autotrophic, woody, and mechanically independent (self-supporting) plants	Many taxa within the dicotyledons, palms among the monocots, a few conifers and gnetums, some cycads and tree ferns.	Mature size and form have often been used to subdivide the tree category. Unfortunately, no consistent definition has been employed.
Herbs	Autotrophic, mechanically independent plants with little or no lignification and secondary thickening of stems or roots	Many dicot and monocot taxa, many ferns; some characteristically epiphytic species are facultatively terrestrial when they fall from the trees.	The giant herbs, largely from the Zingiberales, can be distinguished by size, and in ecological terms may have more in common with trees than the other herbs.
Climbers	Autotrophic, woody, or herbaceous plants, rooted in the soil and dependent on other plants for support, at least in later stages	A wide range of taxa including dicots, monocots (e.g., palms and aroids), gymnosperms (<i>Gnetum</i> spp.), and ferns.	Woody climbers (lianas) are sometimes distinguished from herbaceous ones; means of climbing can also be employed.
Epiphytes	Autotrophic, woody, or herbaceous species habitually growing on other plants and not rooting in the soil	Epiphytes are dominated by three groups—orchids, pteridophytes, and aroids; bromeliads are an almost exclusively Neotropical epiphyte group.	Division into herbaceous and woody forms might be possible. Often, a distinction is made between species on their relative preference for crown and bole locations on their host trees.
Hemiepiphytes	Plant, mostly woody, that begin life as epiphytes but may eventually grow roots down to the ground	Strangling figs (<i>Ficus</i> spp.) are the largest group of hemiepiphytes.	
Plant parasites	Plants that directly parasitise other plants	Direct plant parasitism is confined to the dicots, and with the exception of <i>Cassytha</i> (Lauraceae) is restricted to probably advanced groups. Mistletoes (Loranthaceae and Viscaceae) and related root-parasitic groups (Santalaceae and Olacaceae) and the mostly herbaceous Scrophulariaceae form the two largest groups.	The parasites can be divided into hemiparasites that are chlorophyllous but possess haustorial connection to host xylem (e.g., mistletoes), holoparasites that are achlorophyllous and entirely heterotrophic (e.g., dodders, broomrapes, and Balanophoraceae, and endoparasites that live inside the host and are only visible externally as reproductive structures (Rafflesiaceae).
Mycotrophs	Heterotrophic plants that derive carbohydrate from a fungus; the fungus may derive its carbon from dead material or from another living plant	All orchids are mycotrophic as seedlings, but most become autotrophic as they develop. The small proportion that remain entirely heterotrophic represent the largest group of mycotrophic species. Other monocot mycotrophs include members of the families Petrosaviaceae, Triuridaceae, Iridaceae, Burmanniaceae, and Corsiaceae. Ericaceae, Gentianaceae, and Polygalaceae are the only dicot families with mycotrophic species.	Detailed investigations can distinguish the “parasitic” from the “saprophytic” species but these have been conducted for relatively few of the tropical species.

A total of 942 species were encountered in the 100 × 100-m plot (Balslev *et al.*, 1998). Lower montane forest at 1500 m in Java was estimated to contain 333 species in 1 ha (Meijer, 1959). A single plot of 10 × 10 m in Costa Rica contained 233 species (Whitmore *et al.*, 1985), more than any among eight plots of the same size recorded in Gabon (74–130 spp.; Reitsma, 1988). Duivenvoorden (1994) enumerated all the vascular plant species in a series of ten 0.1-ha plots in Colombia. The most species-rich plot contained 313 species. Gentry and Dodson (1987a) recorded 365 species from 0.1 ha

at Rio Palenque, Ecuador, but this was from 10 noncontiguous subplots. Two other sites in Ecuador, sampled with the same methods, were considerably less diverse, with 169 and 173 species recorded (Gentry and Dodson, 1987b).

Most estimates of plant diversity in tropical forests involve the enumeration of stems above a certain diameter (or girth) at breast height (1.3 m) or above obvious outgrowths, such as buttresses or stilt roots. Many different sampling methods and size limits have been employed in such investigations, but fortunately a few approaches have been applied relatively

consistently and allow intersite comparisons of diversity. Three commonly employed methods of assessing plant diversity in tropical forests produce scales of species-richness values that are comparable, at least in the broad view (Table 4). I used these data to define categories of relative diversity for lowland tropical forests. Forests of very high diversity have thus far only been reported from the New World.

They are known from the lowland forests of the Pacific coast of Colombia in Chocó Province and the Upper Amazon Basin stretching in a belt below the eastern slopes of the Andes from Ecuador to Peru. The occurrence of 250 species in a 1-ha plot near Manaus in the center of the Brazilian Amazon (Ferreira and Rankin-de-Mérona, 1998) countered the impression that the forests of the middle and lower Amazon were of uniformly

Table 4 Categories of plant diversity in lowland tropical rainforests

Species-richness class	No. of species ^a	Examples from different geographic regions ^a		
		Neotropics	Africa	Asia-Pacific
Low	Less than 100	Barro Colorado Island, Panama; ^f San Carlos, Venezuela; ^g Belém, Brazil ^k	Kibale, Uganda; ^e Kade, Ghana; ^e Lopé, Gabon ^f	Mulu (limestone), Malaysia ^o

^pReitsma (1988) (x).^aSpecies richness can be measured in one of three ways: (x) Species represented among the trees and lianas of 10 cm dbh (or 30 cm gbh) or greater on a 100 × 100-m (1 ha) plot; (y) species represented among the first 500 tree and liana individuals of 10 cm dbh (or 30 cm gbh) or greater on a contiguous plot; and, (z) species represented among the trees and lianas of 2.5 cm dbh or greater on a 0.1-ha sample consisting of ten 50 × 2-m transects.^bValencia, *et al.* (1994) (x).^cFaber-Langendoen and Gentry (1991) (x), Gentry (1986) (z).^dFerreira and Rankin-de-Mérona 1998 (x).^ePhillips, *et al.* (1994) (y).^fCondit, *et al.* (1996) (x).^gValencia, *et al.* (1998) (x).^hGentry (1993) (z).ⁱGentry and Emmons (1987) (z).^jGentry (1988) (z).^kBlack, *et al.* (1950) (x).^lCao, *et al.* (1996) (x).^mNewbery, *et al.* (1992) (x).ⁿWright, *et al.* (1997) (x).^oProctor, *et al.* (1983) (x).

lower diversity than the uppermost reaches. High-diversity forests are well represented in the South American tropics and are of similar species richness as the lowland dipterocarp forests of West Malesia and at least some of the lowland forests of New Guinea. To date, only Madagascan rainforests have been shown to attain high-diversity status among those from Africa. The most diverse mainland African rainforests occur in Cameroon and Gabon in West Africa, but these are substantially less rich than many forest sites in the neotropics or the Asia-Pacific region and on a global scale could only be classed as of intermediate diversity. Many sites where detailed ecological research has been conducted, such as Barro Colorado Island, Panama, San Carlos de Rio Negro, Venezuela, and Kibale, Uganda, are low-diversity rainforests. These geographic patterns in local species richness appear to mirror quite closely the tropical regions of the map of plant species diversity per 10,000 km² (Barthlott *et al.*, 1996; see <http://www.botanik.uni-bonn.de/biodiv/phytodiv.htm>).

An important point is that the range of values for diversity within a locale, i.e., an area of approximately identical climate, can cover much of the general range exhibited across wide geographic and climatic gradients. For example, at Caquetá in Colombia total vascular plant diversity in ten 0.1-ha plots was

Table 5 Environmental trends in tree species richness per unit area in tropical rainforest

Number of species increases with total precipitation.
Number of species decreases with increasing seasonality of rainfall.
Number of species increases with soil fertility, although diversity may level off, or even decline, on the most fertile sites.
Number of species declines with altitude.

40–313 species (Duivenvoorden, 1994), at Tambopata in Peru five 1-ha plots had 60–173 species for stems of 10 cm dbh or larger (Phillips *et al.*, 1994), and at Gunung Mulu National Park in Sarawak four plots varied between 73 and 223 species for the same plot and tree sizes as those of the previous example (Proctor *et al.*, 1983). In all these cases the lowest diversity plots were ones on predictably harsher substrates, such as permanently waterlogged soils (Caquetá and Tambopata) or limestone karst (Gunung Mulu). Soil physicochemical properties are highly influential on the composition of the forest community and clearly affect species richness. However, there are also other environmental factors that can lead to gradients in plant diversity (Table 5). Rainfall appears to be

Table 6 Representation of major life-form groups in the floras of different tropical rainforest sites^a

Site	Mean annual rainfall (mm)	Total No. spp.	Percentage of species in major life-form groups

the major determinant of diversity when old-growth sites on freely draining, nonextreme soils are compared. A relatively strong positive correlation between average annual precipitation and diversity has been observed in many tropical data sets (Givnish, 1999), although good data for total plant diversity is lacking so that only estimates for large woody stems can be used. This correlation is evident over the range of true lowland tropical rainforest and is not merely a comparison of diversity between drier forest formations and proper rainforest. Rainfall seasonality (the presence and severity of a dry season) is of key importance, but it is difficult to quantify this from standard meteorological data, and total annual rainfall is a good predictor of diversity in most cases. It is not immediately evident why further increasing the wetness of a wet climate should continue to increase the local species diversity, although highly ombrogenous sites may favor epiphytes. As can be seen from the data presented in Table 6, the proportion of the flora that epiphytes represent increases quite sharply with average annual rainfall.

Why Are Tropical Rainforests so Diverse?

Lowland tropical rainforests undoubtedly represent the zenith of terrestrial biodiversity, probably with more than half the world's biota on less than a twentieth of the land surface. High plant diversity may well be a major contributory factor to the overall abundance of species in the rainforest through the specialization of a myriad of invertebrate species to each plant. However, why are there so many plant species in the tropics? In evolutionary terms, high species diversity must imply many speciation events and relatively few extinctions of species because diversity is the balance between these two processes. Therefore, the tropics may be richer in species than other areas of the world because there has been more rapid speciation here and/or a slower rate of extinction. It is possible that the benign and equable climate of the tropics makes it less likely that a species will become extinct than in the harsher climates elsewhere. The positive correlation between forest diversity and annual precipitation within the tropics also indicates a link between environmental adversity and reduced diversity.

Switching from an evolutionary to an ecological perspective, tropical rainforest diversity maintains a perplexing fascination. A commonly held view of natural communities is that they consist of populations of species in which intraspecific competition is stronger than interspecific competition. In other words, species occupy separate niches within the community and have reached a competitive equilibrium. An equilibrium model of the structure of a lowland tropical rainforest plant community requires that all the species present, including the many species of similar life-form and basic ecology such as canopy trees, or understory treelets, occupy separate niches. Given the simple requirements of plants—light, water, and nutrients from the soil—it is not immediately obvious where so many niches could come from to support the observed diversity. Differences in requirements for reproduction and regeneration may allow more axes from which to partition niches. These niches could be extremely narrow because of the constancy of the tropical environment allowing persistence of small or sparse populations. I suspect, however, that few tropical forest ecologists believe that all the plant species in a forest are ecologically distinct. A more plausible hypothesis is that most species have ecologically equivalent or similar species with which they co-occur. It is worth noting that a high proportion of the species present in a rainforest exist as populations intermingled with those of congenics. For instance, of the 814 tree species recorded from 50 ha at Pasoh, Malaysia, 82% had a congeneric present in the plot and 70% had a congeneric present in the same broad stature class (Manokaran *et al.*, 1992). For descriptive convenience, ecologists may group species into guilds of ecologically similar entities such as pioneer trees or bole climbers, but it must be remembered that these are not necessarily discrete groupings in terms of niche space in the community. They may represent arbitrary divisions of whatever axes of differentiation are being considered.

If competitive equilibrium has not been obtained then something must be preventing competitive exclusion within the community from occurring. One possible process by which this could happen is through frequency-dependent mortality operating within the community setting an upper limit on the abundance of a species and thus making it unlikely that it can totally exclude other species from the

landscape. This compensatory mortality, particularly among tropical trees, is often referred to as the Janzen–Connell effect after the two researchers who independently put forward the hypothesis that species-specific predators could produce the density-dependent mortality required to promote the coexistence of many plant species in a forest. Invertebrate seed and seedling predators, and plant pathogens such as fungi, have frequently been observed to cause severe mortality of germinants and juveniles occurring in high densities near parent trees. Detailed analyses of spatial patterns of sapling mortality on Barro Colorado Island, Panama, showed evidence of compensatory mortality in recruitment for 67 of 84 of the most common tree species (Wills *et al.*, 1997). Rare species, which make up the bulk of the diversity in the forest, may not reach sufficient adult densities to suffer compensatory mortality. However, they may just be too rare to provide statistically significant results with the available data sets. Givnish (1999) hypothesized that compensatory mortality may increase in intensity with rainfall because pest and pathogen populations are less likely to be checked by a dry season in an ever-wet forest. This may explain, at least partially, the observed increase in forest diversity with precipitation.

An alternative nonequilibrium view of the community is that chance is the major determinant of community composition and relative abundance. The majority of species are so infrequent that they very rarely come into direct competition with other ecologically equivalent, similarly sparse species. Chance, and not competitive ability, is an important determinant of which species establishes an adult successfully at a given site because most species are unable to produce enough seeds, disperse them well enough, or survive the early onslaughts of pests and pathogens to ensure that they have a candidate for any vacancy in the community (Hubbell *et al.*, 1999). Many potential episodes of interspecific competition may be won by default, and by competitively inferior species, because no adversaries were present at the right time and place.

At present we have no simple answer to the question of why there are so many species in the rainforests and how they manage to coexist. Nor does it seem likely that there is a simple answer. Probably all the factors mentioned previously, and possibly others not yet considered, are operating within any rainforest but probably not affecting all members of the community simultaneously.

The Value of Tropical Rainforest Plant Diversity

If tropical rainforests are to be conserved, conservationists need to convince a wide range of people that tropical rainforests have sufficient value to merit conservation. In attempting to do so, conservationists face a series of dilemmas. The first is whether to consider value as an economic parameter or not. The global economy hardly has a good record for preventing extinction or supporting sustainable exploitation, but the reality is that people in the tropics exploit the rainforest so that they can improve their standard of living, even if only in the short term. Conservationists can promote the development of a truly sustainable global economy, but in

the meantime they must address the immediate problem of impending extinctions. Purely economic analyses generally favor rapid liquidation of forest resources, although a notable exception was a comparison of exploitation of minor forest products, such as fruits and latexes, with logging and timber tree plantations in Peru (Peters *et al.*, 1989) which showed that the relatively sustainable nontimber production generated greater revenues and thus put the highest net present value on the resource. However, the study has been criticized as being atypical in having a forest with a very high density of fruit and latex trees relatively close to a major population center providing a ready market for the products.

Are there any economic benefits to be gained from leaving rainforest undisturbed? A group of people for which the answer to this question is generally in the affirmative are traditional forest dwellers. Few of the tropical rainforest regions are without people who live in the forest, either making their living by hunting and gathering in the forest or by farming on a small scale, usually as some form of traditional shifting agriculture. Large-scale forest clearance dispossesses the traditional forest dwellers of their entire resource base and often much of their social fabric.

Tourism potential is perhaps the most economically lucrative opportunity offered by virgin tropical rainforest, but fortunately we are not yet in a situation in which every remaining area of forest can attract enough paying visitors to make conservation profitable. However, at a local level, ecotourism probably offers the best hope of generating an income from unexploited forest. Plant biodiversity, in addition to providing the glorious backcloth, is rarely likely to be the focus of ecotourism, although *Rafflesia* may be a notable exception.

The value of the tropical rainforest as a storehouse of potentially useful genetic diversity is probably the best claim for a high intrinsic value to be placed on biodiversity. For vascular plants the potential uses are largely of three main types: medicinal, novel crops, and novel genes for improvement of existing crop varieties. A new drug that is superior to other available medicines can be worth millions of dollars, not to mention that it can have tremendous humanitarian value in the reduction in suffering. New or improved crops also have substantial economic value. Given the massive concentration of biodiversity in the tropics, it is almost certain that superior and economically rewarding new products await discovery in the rainforest. However, searching the haystack for the few golden needles is a difficult, expensive, and often fruitless procedure. Island biogeography theory predicts that a 90% loss of habitat equates to a 10% reduction in diversity. Therefore, the potential economic returns from undiscovered rainforest products seem unlikely to provide strictly economic arguments for preventing the destruction of tropical forests until the area left is very small.

Forests are important for their so-called “ecosystem services”—the amelioration of atmospheric composition, water quality, and local climatic regime among a variety of beneficial emergent properties of the rainforest community. Despite considerable speculation and some very simplistic experimentation, there is no solid evidence that species richness per se has a major influence on these community-level processes. Most species in the rainforest are very rare, so it seems unlikely that the random removal of a certain proportion of

the flora would consistently influence oxygen production, carbon sequestration, nutrient cycling, and transpiration.

In the prevailing international financial framework it is difficult to find a sound, strictly economic, argument for conserving tropical rainforest. When environmental and ecological sustainability become the key goals of the global economy, conservation will make economic sense. The biodiversity of the tropics has a unique and irreplaceable intrinsic value as well as cultural, spiritual, educational, and humanitarian worth to millions of people, many of whom have never been in a tropical rainforest.

The Fate of the Tropical Rainforest

The human population of the tropics has already destroyed the rainforest occupying half the area it would be expected to cover in today's climatic regime. Much of the remaining forest is fragmented into small remnant patches, damaged, burnt, or defaunated. Extensive, relatively pristine forests are largely confined to Amazonia, the Congo Basin, and New Guinea. Most tropical rainforest nations have little remaining forest, and although they generally have designated national parks, forest reserves, or other protected area status, the actual protection that these sites receive is often inadequate to prevent deterioration. There are of course exceptions, and excellent tropical rainforest nature reserves do exist.

There is no sign that the global rates of deforestation in the tropics are declining. Tropical forests are cleared for a variety of purposes and the relative importance of these varies between regions (Bawa and Dayanandan, 1997). In Africa and parts of South America, the demand for land by a large population of poor people who need to subsist on what they can grow leads to deforestation. Clearance for cattle ranching is also common in Latin America. Establishment of plantations for commercial tree crops, such as oil palm (*Elaeis guineensis*) and rubber (*Hevea brasiliensis*), is a more destructive force in the Asian tropics. Human populations continue to grow rapidly throughout the tropics, making it unlikely that the pressure for land for food production or cash crops will decline.

There is increasing evidence that the tropical rainforest community, particularly its botanical component, is more resistant to human disturbance and fragmentation than has been feared. Studies have shown that selective logging does not reduce tree diversity very much (Cannon *et al.*, 1998) and long-isolated forest fragments maintain relatively high proportions of their original floras (Turner and Corlett, 1996). This information is met with some ambivalence by conservationists, who have tended to stress the fragility of tropical forest ecosystems. It is positive and hopeful in that it provides some scientific support to the aspirations for sustainable exploitation of tropical forests and the persistence of the native biota in nations in which only fragments remain. However, there is a real concern that knowledge of this relative robustness will be used as an excuse by those with political power to allow greater levels of exploitation and deforestation, possibly including inside currently protected areas.

From a pragmatic viewpoint, it is obvious that a multiplicity of approaches will be required to conserve the tropical

rainforest biota. Where there are still large areas of relatively undisturbed forest with low human population densities, efforts to establish large inviolate parks are warranted, but in areas with a landscape dominated by human activity the remnant patches of the original forest have an important conservation value in their own context. These fragments may not contain all the original species, but they still support a rich diversity that otherwise might be completely lost. In highly degraded tropical landscapes, which are very common, forest fragments may also play a vital role in the reforestation of these derelict lands by acting as foci for tree establishment and sources of planting material.

Riparian Landscapes

Introduction

Transitional semiterrestrial/semiaquatic areas regularly influenced by fresh water, and usually extending from the edges of water bodies to the edges of upland communities, are often referred to as riparian zones or floodplains (Malanson, 1993; Naiman *et al.*, 2005). Owing to their spatial position, they integrate interactions between the landscape's aquatic and terrestrial components. They are dynamic environments characterized by variable energy regimes, substantial habitat heterogeneity, a diversity of ecological processes, and multi-dimensional biophysical gradients. They are often locations of concentrated biodiversity at landscape, regional, and continental scales (Naiman and Décamps, 1997).

Riparian zones associated with running waters are three-dimensional biophysical structures. They are set in complex ecological and cultural matrices – from headwaters to the sea – that have both surface and subsurface components that are changing over time. Expansion and contraction of riparian zones along rivers occur in relation to precipitation, river flow, and geomorphology. One segment of the channel may be fed largely by upwelling groundwater, whereas at other locations surface runoff may penetrate into bed sediments (alluvium) accumulated over millennia by cut-and-fill alluviation. During flooding, when surface flow may recharge groundwater aquifers and spill out over the floodplains, eroding or depositing sediment in accordance with the energy dynamics of water interacting with geomorphic features, riparian characteristics aid in sediment deposition and the dissipation of erosive energy. During dry periods, when flow in the channel may be maintained only by alluvial and karstic aquifers, riparian characteristics quickly adjust to the environmental regime. Thus, rivers may be viewed as a collection of dynamic multi-dimensional pathways along which aquatic–terrestrial linkages vary spatially and temporally (Rood *et al.*, 2003). Anthropogenic influences contribute greatly to this variation, as river valleys have been foci for human settlements and commerce for millennia.

Fires, drought, flooding, landslides, wind throw, grazing, and other natural disturbances, coupled with human interventions such as logging, urbanization, farming, and damming, alter vegetative patterns and soil–plant nutrient exchange at a variety of scales. This has direct consequences for ecological processes in riparian zones – such as biodiversity, productivity, sediment transport, and live and dead wood recruitment.

In an increasingly human-dominated world, the biodiversity riparian zones must be viewed in a landscape context – that is, as natural-cultural systems (Décamps, 1996; Arthington *et al.*, 2010). Although surface and subsurface patterns and processes act as key drivers for sustaining riparian goods and services, it is human perceptions and cultural representations of landscapes that shape the biodiversity of contemporary riparian zones.

Here, we focus on the biodiversity and unique ecological functions of riparian zones and how these functions are linked to dynamic biophysical processes and interactions across multiple spatial and temporal scales along natural rivers.

Riparian Zones as Focal Points for Biodiversity

River corridors normally possess highly diverse floral and faunal communities and attendant biological processes. These attributes emerge from the unique spatial organization – a mosaic of habitats continually changing in response to variable water flows above and below ground – and biotic responses to the locally variable topography and climate. The net effect is substantial small-scale heterogeneity. Further, the inherent heterogeneity introduced by local topography affects the frequency and duration of inundation, and the local microclimate influences the ability of individual species to flourish, thereby adding even more physical as well as genetic heterogeneity. Collectively, heterogeneity at local scales offers a great variety of conditions for life, making riparian corridors focal points for biodiversity. Riparian diversity is further magnified at the catchment scale since riparian corridors extend from the highest to the lowest elevations above sea level, and the higher elevation riparian zones are numerous, which tends to augment regional diversity.

Studies throughout the world indicate that riparian areas generally have high levels of both of plant and animal diversity. In the Pacific Northwest of the US, 74% of all plant species within one catchment are found in the riparian corridor, which corresponds to only ~3–8% of the catchment depending on topography. According to other reports, all periodically flooded forests in the Amazon basin may have about 20% of the 4000 to 5000 estimated Amazonian tree species, and about 1400 vascular plant species occur along the Adour River riparian corridor in France, representing 30% of the French flora. However, this information may be slightly misleading because comparative studies are seldom undertaken in surrounding uplands. It has been suggested that riparian zones increase regional diversity >50% by harboring different species assemblages, rather than more species, when compared to surrounding uplands.

Many riparian corridors vary in species richness along the river's course, but some do not. There appear to be three types of riverine reaches that fundamentally differ in terms of biodiversity: Naturally constrained river reaches increase in biodiversity downstream, whereas braided reaches have relatively low diversity and meandering reaches have high biodiversity. In general, longitudinal studies show that plant diversity generally increases downstream, with the peak reached in the piedmont (transition zone between mountain and lowland domains) as the riparian zone widens, or at major tributary

Figure 1 Floodplain profiles of two rivers in natural conditions: The river Beaton, British Columbia, Canada, above (after Nanson and Beach, 1977) and the Río Manu, Peru in the upper Amazon basin, below (after Salo *et al.*, 1986). Such relationships between landforms and forest succession characterize riparian forests along rivers under natural conditions all over the world (Décamps, 1996).

deltas. Additionally, natural gradients in nutrient subsidies between other ecosystems and riparian zones can affect biodiversity. In coastal British Columbia and Alaska nutrient subsidies from spawning Pacific salmon (*Oncorhynchus* sp.) increase nutrient loading to riparian soils shifting plant communities toward nutrient-rich species, which in turn decreases plant diversity (Hocking and Reynolds, 2011). These effects are mediated by interactions between salmon density and the physical characteristics of watersheds.

These catchment-scale patterns suggest a maximum diversity at an intermediate level of natural disturbance, which induces considerable spatial heterogeneity. However, other physical attributes (e.g., channel gradient, lithology, level of confinement) and local climate also modify site-specific species richness and can result in no net trend in longitudinal species richness. Lateral patterns in plant diversity also generally peak at intermediate levels of natural disturbance

and moisture availability. Diversity is often low immediately adjacent to the river, increasing with local elevation and geomorphic complexity, and then declining slightly upslope of the riparian-upland interface, although there are variations to this generalization (Van Pelt *et al.*, 2006). Factors controlling species expression are also keys to understanding riparian plant diversity: Flood frequency, site productivity, and spatial complexity have been related to plant species richness (Figure 1). In contrast, human induced disturbances like deforestation and farming tend to reduce both levels of biodiversity and the processes promoting diversification.

Overall, riparian soils appear to have an impressive diversity. There may be as many as 10,000 species of ectomycorrhizal fungi, >3000 species of bacteria, >5000 species of nematodes, and tens of thousands of species of mesofauna (mites, collembolans) and macrofauna (ants, termites, earthworms). Aboveground faunal diversity is better known but

Figure 2 Three-dimensional representation showing relations among species richness, flood frequency, and topographic variation for riparian areas in southeast Alaska (Pollock *et al.*, 1998).

it is far from being completely understood. Reasonably comprehensive studies exist for some groups, especially birds, whereas knowledge about other groups is nearly nonexistent (e.g., most invertebrates). Flooding certainly affects invertebrate community dynamics – distribution, abundance, and diversity – with species richness often increasing with elevation above the river even though flood duration will affect groups differentially (Figure 2). Among the invertebrates, spiders (Arachnida) and beetles (Coleoptera) are the better-investigated groups.

In many areas, a large proportion of vertebrates utilize the riparian zone, but it is not always apparent whether individual groups are more or less diverse there (Sabo *et al.*, 2005). For example, in western Oregon and Washington (USA), 87% of the 414 resident species of amphibians, reptiles, birds, and mammals use riparian zones or wetlands, but only 10% use specialized habitat within riparian zones. More is known about species depending on the streams for foraging or reproduction than about species using riparian zones only occasionally. Certainly, amphibians are more diverse in riparian zones because of their reproductive needs. For reptiles, birds, and mammals, it depends on the local environment and specific life history needs.

The best information available is for birds (Gilles and St. Clair, 2008). In the drier western US, bird diversity at the site scale (alpha) is generally high relative to the number of potential species. Between habitats, diversity (beta) varies across a catchment, with riparian assemblages differing most from upland assemblages at the highest and lowest elevations. This pattern is attributed to enhanced avian movements within the riparian corridors. The corridors for bird movements, in turn, facilitate faunal mixing on a broader scale, increasing regional diversity (gamma) within landscapes.

Mammal diversity in riparian zones appears to be great, but this may be deceptive. Mammals are highly mobile, and many, such as moose and elk in winter, make frequent use of riparian zones for feeding and cover. Certainly bats feeding on emerging stream insects are abundant at times, and other

medium-sized predators (badgers, foxes, cats) come to feed and drink. Browsers and grazers, as well as rodents and shrews, are often abundant, but most can be found in the uplands too.

Are riparian zones more diverse than the surrounding uplands? The answer is that it depends on the environmental setting and the taxon being considered. Ecological theory would suggest that, in general, riparian areas are highly diverse because of their mosaic structure, presence of refugia, broad ranges of environmental settings and species assemblages.

Riparian Zones as Buffers Against Nutrient Pollution from Upland Runoff

The nutrient buffering characteristics of riparian zones are well known, and may stem from their biodiversity (Lowrance *et al.*, 1995; McClain *et al.*, 2003). As a result, the effectiveness of riparian zones as nutrient filters for water flowing from agricultural catchments to streams has led to major government-supported programs in North America and Europe to conserve and restore riparian buffers. The filtering capability of riparian zones is due to their position in the landscape, and to their geomorphic, hydrologic, and biotic processes. Since riparian zones lie at the interface of terrestrial and aquatic ecosystems, virtually all surface and shallow subsurface runoff in catchments must pass through them in order to reach the stream channel. It has been hypothesized that the diversity of plants contributes to the efficient uptake of nutrients.

Riparian zones are generally planar, with lower gradients than surrounding uplands. This, plus the baffling effect of riparian vegetation, dissipates the kinetic energy of surface flows during storms and causes entrained sediments to be deposited. This is an especially effective mechanism for retaining particulate phosphorus and the chemical pollutants associated with sediment particles. The capacity of riparian zones to retain dissolved nutrients like N, P, Si, Ca, and Mg is controlled by hydrologic characteristics (e.g., water table depth, water

residence time, and degree of contact between soil and groundwater) and by biotic processes (e.g., uptake and biogeochemical transformation by diverse plants and microbes). The relative influence of these factors depends on soil characteristics, nutrient input rates, and vegetative and microbial diversity.

Elucidating the volume and pathway of water moving through riparia is fundamental for understanding nutrient removal and retention (Junk *et al.*, 1989; Tockner *et al.*, 2000). If local groundwater passes beneath the rooting zone or if extensive piping occurs, the roots of riparian vegetation and associated microbes cannot access the nutrients. Riparian vegetation along small streams normally has good access to the water table, and many studies have shown that in those situations riparian vegetation can act as buffers for nonpoint-sources of N and P. However, hydrologic pathways are often more complex along larger rivers, especially where deposits of coarse alluvium are extensive.

Riparian zones are known to be especially effective at protecting surface waters from nitrate runoff (Lowrance *et al.*, 1995). Early studies documented total nitrogen retention by riparian zones ranging from 67% to 89% of total up-slope inputs. Wetlands and soils are also sites of N retention, but a plethora of studies have shown focused removal of nitrate in groundwater moving laterally through riparian zones. In a large-scale study of N budgets in 16 catchments covering 250,000 km² of the northeastern US, river exports of N accounted for only 25% of the total N inputs to the catchments, implying that most of the N was retained in some manner.

Candidate mechanisms preventing nitrogen flowing through riparia from entering streams include denitrification, assimilation and retention by the vegetation with the uptake by biota followed by storage in organic detritus. Denitrification is invoked most often as the primary mechanism of nitrate retention and the most important given that N is removed permanently from the system and returned to the atmosphere as N₂ and N₂O. However the extreme spatial and temporal variability of denitrification rates in riparian zones makes it difficult to determine accurate fluxes and to extrapolate these to wider areas. In addition to nitrate, saturated conditions, available carbon, topography, and soil grain size (i.e., water logging potential) are pertinent environmental factors for denitrification.

Plant uptake results in a short-term accumulation of nutrients in nonwoody biomass and a long-term accumulation in woody biomass. Riparian forests are especially important sites for biotic accumulations of nutrients because transpiration may be quite high, increasing the mass flow of nutrient solutes toward root systems, and because morphological and physiological adaptations of many flood-tolerant species facilitate nutrient uptake under low-oxygen conditions. Thus, assimilation by the diverse riparian forest community could be the primary mechanism of nitrate removal from groundwater during the growing season. Nitrogen removal efficiency by riparian buffers is mainly positive across a wide range of climate conditions, nitrate inputs, soil characteristics, and vegetative community types.

The current consensus that most riparian zones effectively remove nitrate from subsurface water is based largely on studies where groundwater inputs are restricted to shallow subsurface

flow paths by impermeable layers that force maximum interaction with riparian soils and vegetation. Limited research suggests that there is less effective nitrate retention in riparian areas connected to large upland aquifers where riparian hydrology is often dominated by surface transport or ground water transport below rooting zones. Additionally, it has been discovered that considerable nitrogen can be released from riparian zones to streams as dissolved organic nitrogen. The importance of this pathway, and the forms and subsequent fates of the organic nitrogen are unknown. Collectively, the evidence assembled so far raises doubts about all riparian zones being efficient filters for nutrients – some may be leaky whereas others release nutrients after they have been transformed to organic matter – and if biodiversity might have a role.

Riparian Zones as Buffers Against High In-Stream Nutrient Levels

In much the same way that riparian zones intercept and retain nutrients from upland overland and subsurface runoff, they may also intercept and retain nutrients flowing in adjacent streams. The same mechanisms of N and P removal are at work, including biotic uptake, physical adsorption, and microbial denitrification, and the effectiveness of riparian buffering depends on the characteristics and biodiversity of riparian soils, vegetation, and connectivity between the river and riparian zone along surface–subsurface exchange pathways. Water in streams exchanges continually with the interstitial waters of bed and bank sediments in what may be viewed as a mosaic of surface–subsurface exchange patches. This zone of mixed surface and subsurface waters is known as the hyporheic zone and may extend from a few centimeters to a few kilometers from the channel margin. The volume of surface water moving along subsurface flow paths can be equal to or greater than that moving in the channel.

Hyporheic flow paths act as both sources and sinks of nutrients to streams and the degree of hyporheic influence on river nutrient levels depends on the extent of hyporheic zones, the fraction of river flow diverted through them, the residence time of individual flow paths, and the specific biological and biogeochemical processes operating along flow paths. In general, streams with greater hyporheic exchange – and possibly greater plant diversity – tend to retain and process nutrients more efficiently. Additionally, because the amount of surface–hyporheic water exchange relative to channel volume decreases exponentially with increasing channel size, the efficiency of nutrient removal linked to hyporheic exchanges tends to decrease with increasing stream size. The most important sites of nutrient retention therefore lie in the low-order stream networks of any river basin. For example, first order N-retention rates in headwater streams of the Mississippi River basin average 0.45 day⁻¹, whereas the rate of removal in the mainstem river is two orders of magnitude less, or 0.005 day⁻¹.

Plant cover also influences the efficiency of riparian zones in filtering nutrients and pesticides (Lowrance *et al.*, 1995). A riparian zone vegetated with poplar is more effective for winter nitrate retention than one vegetated with grass. Some trees are better than others in filtering nitrate: *Populus x*

canadensis effectively removes nitrate from saturated soils with a subsequent accumulation of nitrogen in root biomass. Roots of alder, willow, and poplar seem to favor colonization by proteolytic and ammonifying microorganisms and, particularly for alder roots, to inhibit nitrifying microorganisms. It follows that changing plant cover may affect water quality.

Riparian Zones as Buffers Against Suspended Sediments

Riparian vegetation also facilitates the removal of suspended sediments – along with their nutrient, carbon or pollutant contents – from overland flow whether from the uplands or from the adjacent river. A diversity of structural sizes and resilience to flow aids this process. Sediments and sediment-bound pollutants carried in surface runoff are effectively deposited in mature – and diverse – riparian forests and in streamside grasses. Riparian areas remove 80–90% of the sediments leaving agricultural fields in North Carolina. Sediment deposition may be substantial in the long term, with coarser material deposited within a few meters of the field–forest boundary, and finer material deposited further into the riparian forest. Grassy areas are especially effective as they often transform channelized flows into expanded shallow flows, which are more likely to deposit sediment. However, the performance of grassy vegetation seems to be highly variable and to be of short duration when several floods occur within a limited period.

Removal of fine sediment from runoff by riparian zones occurs as a consequence of the interactive processes of deposition and erosion, infiltration, and dilution. This is important because fine sediments carry higher concentrations of labile nutrients and adsorbed pollutants. In forested catchments, with relatively low nutrient concentrations, fine sediments in riparian zones can be sources or sinks for nutrients, depending on how oxidation–reduction conditions affect absorption/desorption to fine particles. For example, the riparian zone of a small deciduous forest stream in eastern Tennessee (USA) was a net source of inorganic phosphorus when dissolved oxygen concentrations in riparian groundwater were low, but was a sink when dissolved oxygen concentrations were high.

In contrast to nitrogen, phosphorus adheres strongly to particles and considerable movement is normally associated with sediment flux. Reductions of 50–85% in total P are observed, with the greatest removal occurring in the first few meters of the riparian zone. Results for soluble P in surface runoff are less consistent due to variability in water flow (i.e., sheet flow, channel flow, or percolation). In general, significant amounts of phosphorus may first accumulate in riparian zones but then be transported to aquatic ecosystems in a different form via shallow groundwater flow, possibly as a result of increased decomposition of organic matter.

Only limited research has been conducted on subsurface P transport in riparian zones. However, the same environmental conditions leading to redox gradients in soils that are responsible for nitrogen removal by denitrification also mediate desorption and release of phosphorus. Although riparian zones may act as effective physical traps (sinks) for incoming particulate phosphorus, they may enrich runoff waters in available

soluble phosphorus. Finally, unlike nitrate, phosphorus removal by soil retention and biotic uptake results in accumulation within the system. Consequently, the long-term performance of riparian zones receiving high P inputs remains unclear.

Riparian Zones as Sources of Energy for Adjoining Aquatic Systems

By far the most thoroughly investigated and best understood connection between riparian and stream food webs is via the transfer of riparian plant litter to streams (Wallace *et al.*, 1997). Riparian organic matter inputs represent highly diverse allochthonous sources of energy as opposed to the autochthonous organic matter contributed by aquatic primary producers. In low-order streams beneath closed-canopy riparian forests the influx of carbon from riparian plant sources, both surface and subsurface, may amount to 80–95% of total organic carbon influx to streams. Although the area-normalized flux of riparian litter to river systems decreases downstream, the total amount and diversity of riparian litter input to the river continues to rise and varies as a function of channel morphology and riparian forest structure and composition.

Once in the stream, riparian organic matter is decomposed by a variety of specially adapted microbial and invertebrate fauna (Dang *et al.*, 2005). When litter (mainly leaves and needles) first enters streams there is a brief period (a few days) of rapid leaching in which 25% or more of the initial dry weight can be lost. Biotic decomposition is initiated by hyphomycete fungi that break up the litter's structural integrity by secreting enzymes to hydrolyze cellulose, pectin, chitin, and other difficult-to-digest compounds. Fungal community composition is closely tied to the riparian forest, and fungal species diversity has been positively correlated with riparian tree richness. With time fungi give way to bacteria as the dominant microorganism in the decay process. Decomposition rates are driven by substrate quality, stream nutrient concentrations, redox conditions, and temperature. Fungal decomposition alone can fragment leaves into flakes of finer particulate organic matter within weeks. This fragmentation process is critical to energy dispersion in streams and rivers because finer fragments tend to be more mobile and to therefore fuel metabolism in downstream river sections. Microbially colonized litter has higher nutrient concentrations than noncolonized litter, and is therefore the preferred choice of macroinvertebrate consumers – shredders and collectors such as caddis flies and black flies – that make up the next link in aquatic food webs.

Riparian arthropods are also important energy sources to stream consumers (Nakano *et al.*, 1999). Arthropods fall into streams from overhanging foliage by accident and the flux is proportional to arthropod abundance in the canopy. It is also postulated that the diversity of the arthropod flux is related to plant diversity. Arthropods may also wash into streams and rivers during overland flow events. The normalized flux (per square meter of channel area) is higher in smaller streams flowing beneath a closed riparian canopy but even in larger streams and rivers the flux may remain substantial at the channel margins. Once in the aquatic system, riparian arthropods are consumed by drift foraging fish and may

constitute a major proportion of their diet. Riparian-derived arthropods are higher quality food than riparian litter and are directly available to top consumers such as fish. Experimental evidence shows that withholding this energy input from streams has consequences that reverberate through aquatic food webs and ultimately upset the basic composition of the stream community.

Energy flows in both directions across the terrestrial–aquatic interface, and riparian food webs are also subsidized by aquatic resources. The emerging adults of aquatic insects are an important energy source to a variety of riparian arthropods, and this energy subsidy is passed to higher trophic levels by the lizards, bats, shrews, and birds that consume riparian arthropods. Riparian arthropods inhabiting resource-scarce habitats such as exposed gravel bars and desert riparian environments appear to rely almost exclusively on aquatic prey. For example, emerging aquatic insects composed 80–100% of the diet of certain staphylinid and carabid beetles and about 50% of the diet of lycosid spiders inhabiting gravel bars of the Tagliamento River in NE Italy.

Reciprocal energy subsidies such as these are especially important over the course of the year in temperate regions due to strong seasonal variability in the emergence and abundance of different insects. For example, aquatic arthropod abundance peaks following ‘leaf-out’ of riparian forests in spring and defoliation in autumn whereas riparian arthropod abundance peaks during the summer when forest productivity is maximal.

Large Animal Influences on Riparian Zones

Large animals influence nutrient and energy flows by consuming and redistributing energy and nutrients within riparian zones as well as across adjacent system boundaries, and maintaining their natural population dynamics are important for riparian biodiversity (Helfield and Naiman, 2006). Most importantly, large animals may alter the hydrologic and geomorphic characteristics of riparian zones, causing fundamental changes in energy and nutrient cycles, and altering plant community composition and structure.

Animals that pond water, dig holes, trample plants, or move materials cause fundamental geomorphic changes. For example, hippopotamus (*Hippopotamus amphibius*) increase the ponding of water in African stream networks by creating and maintaining deep pools and forming trails between channels and adjacent terrestrial feeding areas. Beaver (*Castor canadensis* and *C. fiber*) profoundly influence the short- and long-term structure, function, and diversity of riparian zones of drainage networks in the boreal forests of northern latitudes by cutting wood and building dams. In catchments where beaver are abundant there may be 2–16 dams per kilometer of stream length, and each dam may retain between 2000 and 6500 m³ of sediment. Ponds are eventually abandoned as they fill with sediment or as local food resources are depleted and, once abandoned, dams fail and ponds drain to produce nutrient-rich wetland meadows.

Animals browsing riparian and aquatic vegetation strongly influence riparian community structure, soil development, and propagule dispersal. Animals that browse selectively keep

preferred plant species from dominating the plant assemblage and thereby provide an advantage to species not browsed. For example, moose (*Alces alces*) prefer willow (*Salix*) and poplar (*Populus*), thus giving a competitive advantage to white spruce (*Picea glauca*), which is not browsed.

The actions of all large herbivores influence the below-ground components of riparian systems as well, with consequent effects on interactions that determine long-term ecosystem function. For example, grazing activities that stimulate the growth of early successional species, and therefore retard succession, help to maintain higher belowground productivity.

Pacific Salmon Influences on Riparian Zones

A remarkable example of the consequences of animal-mediated nutrient and energy flows in riparian zones is the migration of salmon (*Oncorhynchus* spp.) from the North Pacific Ocean to spawning areas in fresh water. Migrating Pacific salmon transport marine-derived (MD) carbon and nutrients upstream and, on death after spawning, hydrologic and animal pathways distribute these elements throughout aquatic and riparian systems (Bartz and Naiman, 2005; Naiman *et al.*, 2009). In an important system-scale feedback, fertilization of riparian plant communities with MD-nutrients enhances the growth of some riparian plants. This may lead to reduced diversity among riparian plants, but it positively influences salmon over the longer term by supplying stream organisms with an increased supply of nutritious litter and by improving salmon habitat via an influx of large diameter riparian-derived wood.

Historically, spawning salmon represented a flux of nearly 7000 Mt of nitrogen and more than 800 Mt of phosphorus to rivers in California, Idaho, Oregon, and Washington. Although fluxes have been reduced by >90% during the past century as populations have declined, salmon still are an important source of nutrients to many river and riparian systems of Canada, Alaska, Russia, and Japan.

Maintaining Riparian Biodiversity

There are four principal categories of threat to the biodiversity of riparian zones – flow regulation, pollution, climate change, and land use alterations (Table 1); all are linked and exacerbated by the modification of river flows and wetland inundation regimes (Rood *et al.*, 2010). One of the most promising strategies for integrating freshwater management into the broader scope of ecological sustainability is the provision of ‘environmental flows’ – the flows left in rivers, or restored to developed rivers, to sustain key ecological and societal values. Other terms, such as ‘in-stream flows,’ ‘ecological flows,’ ‘environmental water allocations,’ and the ‘normative flow regime,’ convey much the same concept. Environmental flows describe the quantity, timing, and quality of water flows required to sustain freshwater and estuarine ecosystems and the human livelihoods and well-being that depend on these ecosystems, including biodiversity. There is now wide recognition that a dynamic, variable water regime is required to maintain

Table 1 Summary of the major types of anthropogenic environmental change and their principal effects on riparian zone biodiversity

<i>Environmental change</i>	<i>Principal effects on riparian zones</i>
<i>Flow regulation</i>	
Flow regime	Alters community composition and successional processes; loss of life history cues
Dams	Lotic to lentic; inundation above dam; altered flow, nutrient, sediment, and temperature regimes below dam
Withdrawals	Lowers water table; alters flow regime; decreases alluvial aquifer recharge; system simplification
Channelization and Dredging	Lowers water table; desiccates riparian forest causing terrestrialization and change in community composition; possible decline in biodiversity
Levees	Isolate rivers from floodplains, thereby reducing hydraulic connectivity laterally and vertically. Constrain channel migration; alter riparian successional trajectories
<i>Pollution</i>	
Nutrients	Increases productivity; shifts community composition toward tolerant species; organic loading leads to redox changes
Toxic materials and acid rain	Decreases productivity; declining biodiversity; system simplification; shifts community composition toward few tolerant species
<i>Climate</i>	
Precipitation	Modifies entire flow regime, groundwater-surface water exchanges, and channel morphology and stability; loss of life history cues
Temperature	Spatial patterns and phenology of riparian species are changed
<i>Land use</i>	
Vegetative cover	Modifies albedo and feedbacks to climate; changes local microclimate and successional trajectories
Invasive species	Introggression and hybridization; increased competition for space and resources; may reduce biodiversity
Resource management	Usually alters successional trajectories and community composition

the native biodiversity and ecological processes characteristic of every river and wetland ecosystem. Yet, it remains a challenge to translate this 'natural flow regime' paradigm into quantitative environmental flow prescriptions for individual river reaches from source to sea (Mahoney and Rood, 1998). These challenges are receiving wide recognition and, in many cases, are being met; thereby maintaining biodiversity and other riparian characteristics.

Riparian areas are often prioritized for protection to preserve specific services described in the preceding sections and also to preserve ecological and evolutionary processes important in conserving and generating biodiversity in altered landscapes. In their unique position along waterways connecting other landscape features, dynamic riparian areas provide refugia and corridors of movement for wildlife and plants and transfer pathways for energy and nutrients. The dynamic disturbance regimes of riparian areas also impose a continual stimulus for plant diversification. Riparian buffers have been shown to preserve and stimulate heightened biodiversity in agricultural and other modified landscapes. These functions may be threatened, however, by invasions of alien plant species which can reduce biodiversity and modify natural processes. Maintaining key components of the natural flow regime is effective in reducing alien invasions.

Conclusions

Riparian zones are highly complex physical and biological systems that both harbor significant biodiversity and facilitate biodiversity conservation across landscapes. Their complexity, biodiversity, and distinctive ecological functions are maintained through strong spatial and temporal biophysical connectivity with adjacent riverine and upland systems. Water, sediments,

and nutrients enter riparian zones from adjacent uplands and streams, mixing and reacting along dynamic surface and sub-surface flow paths (Van Pelt *et al.*, 2006). Under normal flow conditions the biodiverse riparian zone retains a significant portion of these materials and generally returns chemically purer water to streams and rivers. At the same time riparian zones are important sources of energy to both upland and aquatic systems in the form of plant and insect tissues. Many stream food webs fundamentally depend on these resources and many upland animals depend on them as important subsidies to their diets. At the same time, riparian communities benefit from the enhanced productivity of adjoining ecosystems (especially aquatic systems) through physical and biotic feedbacks that return a portion of that productivity to riparian zones in the form of organic matter and nutrients.

The unique biodiversity and ecological functions of riparian zones are linked to dynamic biophysical processes and interactions across multiple spatial and temporal scales. Maintaining these interactions and the connectivity driving them is a fundamental requirement for maintaining healthy riparian zones and the many services they provide; effective management requires maintaining connectivity, both in the timing and extent of flows as well as in the movements and types of animals.

Glossary

Allochthonous Referring to the production of organic matter outside the ecosystem; in streams and rivers, this would be inputs from the upstream watershed.

Autochthonous Referring to the production of organic matter within the ecosystem, for example, primary production by aquatic plants.

Cultural eutrophication The acceleration of nutrient overenrichment caused by humans; it can be caused by direct, point-source pollution (sewers) or by diffuse, nonpoint-source pollution (such as fertilizer runoff from farm fields).

Hyporheic zone The area of saturated soils beneath a stream or a river channel; it interacts with the stream

through the processes of hydraulic upwelling and downwelling.

Riparian zone The vegetated areas on either side of a stream or river, with saturated soils usually underlying aerated soils.

River continuum concept The first of a series of conceptual, unifying models to explain and predict the structure and function of river ecosystems.

Stream order A numbering system to denote stream size within a network of streams. There are several stream order systems. Stream order is also dependent on the scale of observation.

Watershed or catchment A unit of landscape in which precipitation drains to a common stream or lake; alternatively, a watershed is the divide between catchments.

Introduction

Rivers are the sinuous conduits of overland flow that drain the world's continents. They displace very little of the world's land area and their standing stock of water is small relative to other hydrologic storages. Of the estimated 1,385,984,610 km³ of global water, the average volume of rivers composes about two ten-thousandths of 1%, or 0.006% of the freshwater supply (Maidment, 1993). Nevertheless, rivers are of disproportionate importance in terms of geomorphology, ecology, and biodiversity, for they serve as transport vectors for sediments, organic matter, nutrients, and species. In contrast to the image of a river as a pipeline from the source to the mouth, river networks form bifurcating, fractal patterns through the landscape that are among the most complex in nature. Along any reach of the river channel, a fully three-dimensional world lies between the riverbanks; therein are found habitats in which organisms form ecological communities and process energy and matter in various ways, depending on where the reach is located. Because of the intimate connections of rivers with the landscape, the burgeoning pressures of human-accelerated environmental change are becoming particularly acute in these systems.

Anatomy of Rivers

To a hydrologist, the basic unit of the landscape is the catchment or watershed, in which water organizes itself into flow-paths. Watersheds are formed by the various forces of continental uplift and wearing down (weathering) of the bedrock by water and wind. Geomorphologically, vegetation

within watersheds plays a dual role: It aids in weathering and conversion of rock to soils and it retards surface runoff, diverting some of it to gaseous water vapor by evapotranspiration. Watershed boundaries, or divides, are those more resistant zones where water flows either one way or the other into alternative drainages. The Continental Divide in the US separates the western drainages (which flow into the Pacific Ocean) from those (principally the Mississippi) that drain east or south. Divides at the continental scale can often limit the flow of species, but the process of species flow is affected at all scales of watersheds.

Watersheds and their accompanying flowing waters are organized hierarchically, that is, smaller watersheds usually form into larger watersheds (unless a physical boundary prevents this), which in turn may form parts of regional drainages. Hydrologists in the 1940s and 1950s recognized that streams and rivers form drainage networks and defined topological metrics to describe these. The most common metric is stream order. Although there are various definitions of order, Strahler (1952) considers that a first-order stream has no tributaries, a second-order stream is formed at the meeting of two first-order tributaries, a third-order stream at the meeting of two second-order tributaries, etc. Shreve's link magnitude system (Shreve, 1966) defines the magnitude of a stream, downstream of the meeting of two streams, as the sum of the magnitudes of those streams. It should be noted that order is inevitably related to the scale of the map on which the stream and its tributaries are plotted (typically, in the US, the smallest streams delineated at 1:24,000 scale USGS topographic maps are considered first-order streams, but higher resolution maps produce higher order streams). This is a

characteristic of the fractal nature of drainage networks (Rodríguez-Iturbe and Rinaldo, 1997). Another metric is the bifurcation ratio, or the ratio of first- to second-order, second- to third-order, etc. streams within a drainage network. The drainage density, or the ratio of cumulative length of streams (L) to watershed area (L^2), is a third measure of network organization. High bifurcation ratios might indicate the presence of many small streams, and in conjunction with a high drainage density, also describe a highly dissected landscape. More complex models, which take into account differences in elevation, geology, and soils, provide even more detail for water flow and habitat creation.

Early models of watershed hydrology assumed that precipitation events saturated the soils, producing overland flow, beginning from the base of a drainage and moving uphill, much like filling a bathtub. However, in the 1970s, the variable source area model, in which the flow originates from source areas that expand and contract in different parts of the watershed in response to the dynamics of precipitation and drainage characteristics, gained acceptance. Considerable overland flow during a storm is actually water that had been stored in the soil, which is displaced by the new water coming in.

From an ecological perspective, the multitude of geomorphologic forms and flowpaths gives rise to a similar multitude of habitats and ways for matter to be transformed, at scales ranging from the microscopic to the entire basin. A typical cross-sectional view of a stream is given in Figure 1.

In this figure, it is clear that the stream is in contact with several areas: A zone of saturated sediments below, called the hyporheic zone; an area with emergent mud or gravel bars overlying saturated soils, called the parafluvial; and beyond that a zone of bankside vegetation, also in contact with saturated soils, the riparian zone. In upland streams, where the terrain is steep and rugged, these zones may be compressed around the stream channel, but farther downstream the zones may spread out across the floodplain that was carved out over geological time by the flowing water.

Hynes (1975) was among the first stream ecologists to point out the close connection between rivers and their

watersheds. As systems, rivers and streams are inherently open and serve both as connectors, transporters, and processors of material. Among the biological connections of streams and watersheds are the inputs of organic matter from vegetation: leaves, insect frass, partial, or entire trees (which form debris dams). Water does much of the physical work in carving channels and carrying sediment, but organisms mediate this by regulating the rates of mineral use and transport, fixing organic matter and passing it along the food chain, and even altering landforms so that hydrology is affected (e.g., the work of beavers).

Energy and Matter Transformation (Biogeochemistry)

From a biogeochemical standpoint, rivers differ from other ecosystems in at least three important ways: First they are flowing systems that provide a source of kinetic energy, as well as externally produced nutrients, to resident organisms. Second they are spatially complex and extensive systems, with a relatively large interfacial connection to contiguous terrestrial ecosystems. Such a large buffer zone has significant implications for processing nutrients and other fluxes into the river. Finally, as discussed in the previous section, they are transitional systems, changing in nature from small, shallow, flashy first-order streams that are closely connected to the landscape, to large, relatively deep and steady rivers that may be tidally influenced as they become estuarine in nature near their mouths. The interplay between light, nutrients, and turbulent energy and circulation structures the biotic community, and this structure changes along the river from the sources to the mouth.

Riverine ecosystems are fueled by inputs of nutrients, including carbon, nitrogen (N), phosphorus (P), and silicon (Si). Nutrients that are available to primary producers must generally exist in inorganic (mineral) forms. In pristine watersheds, rock weathering and decomposition of organic material in forests, grasslands, and soils provide the sources of these nutrients. In most watersheds today, nutrient loading is dominated by anthropogenic inputs, including fluxes from the

Figure 1 Cross-sectional view of the stream channel and zones that interact with it. Reproduced from Fisher SG, Grimm NB, Marti E, Holmes RM, and Jones Jr. JB (1998) Material spiraling in stream corridors: A telescoping ecosystem model. *Ecosystems* 1: 19–34, with permission from Springer.

atmosphere, agricultural and urban fertilizer applications, N fixation of crops, and net food and feed transfers across watershed boundaries. These loads can be collectively termed Net Anthropogenic Nutrient Inputs (NANI) and simple accounting methods are used to estimate them, especially for N and P (Howarth *et al.*, 1996, 2011; Boyer *et al.*, 2002; Russell *et al.*, 2008; Hong *et al.*, 2011). Atmospheric deposition of nutrients from local or distant agricultural, industrial, and automotive sources occurs via rainfall and dust. Within the watershed, fertilizer from agricultural and urban applications enters rivers in surface runoff and groundwater; discharges of sewage treatment plants and industry provide other sources. Frequently, nutrients also enter rivers in various organic forms (i.e., as byproducts of other organisms, such as soil particles, plant and animal remains, and feces). Sources of organic nutrients associated with human activity include untreated sewage and manure runoff from farms. Organic nutrients entering a river segment from the watershed upstream augment the local primary production of biomass within it to fuel heterotrophic organisms. Such external sources are termed allochthonous as opposed to the autochthonous production occurring within the river. Regardless of whether nutrients enter rivers in organic or inorganic forms, excessive loading can result in accelerated riverine metabolism in which organic matter is consumed in respiration, with a consequent increased biological oxygen demand (BOD). When BOD exceeds the local oxygen supply in a reach of the river, available oxygen levels may decline precipitously (resulting in the oxygen sag curve downstream of nutrient sources familiar to environmental engineers), with catastrophic results to riverine organisms. Such anoxic zones typically resemble the popular image of polluted waters: smelly masses of decaying algae, fish kills, and greatly reduced biodiversity.

Because organisms require nutrients in particular ratios (in oceanography, these are termed Redfield ratios after their discoverer Redfield (1890–1983)) to maintain their metabolism, deviations of environmental concentrations from these ratios can result in species shifts. For example, the shift of the available N:P ratio below the Redfield ratio of 16:1 (moles N per mole P) in fresh waters is often associated with the onset of a bloom of cyanobacteria (blue–green algae) that are capable of fixing N from the atmosphere. Depletion of silicate below the Si:N molar ratio of 1:1 has been observed to shift the dominant species of algae from diatoms (which require silicate to synthesize their siliceous skeletons) to species that do not utilize silicate. Such species shifts are sometimes associated with nuisance algal blooms.

It must be emphasized that the dominant physical controls of riverine ecosystems change drastically as stream order increases. The ecosystem of the shallow, well-mixed, intermittent stream is controlled almost completely by weather and the nature of the contiguous terrestrial ecosystem – geology and soils, nutrient processing in the riparian zone, light levels established by the degree of canopy closure, etc. Near its mouth, the river is deeper and broader and influenced by the sea. Relatively dense seawater meets the lighter freshwater, sometimes resulting in stratification, which, together with the effects of the tide, yields complicated patterns of circulation. The cumulative sediment load of the watershed results in decreased water clarity and increased sediment deposition (the deltas of

many large rivers). The combined workings of internal circulation and turbidity govern the light and nutrient fields of the water column as well as the distribution of biological communities in ways that are not completely understood at present.

Different Conceptual Models of Riverine Ecosystems

Beginning in the 1970s, synthetic conceptual models of rivers began to be developed as part of the ongoing movement to understand the world's ecosystems, under the auspices of the International Biological Programme (IBP). One of the fundamental insights that came to the fore was the necessity of integrating stream ecosystem dynamics over a range of spatial and temporal scales.

River Continuum Concept (RCC)

The RCC (Vannote *et al.*, 1980) originated as a theoretical concept to organize and predict the structure and function of riverine ecosystems from source to sink. The premise is that river ecosystems are dominated by the physical factors that create the drainage network and that ecological communities tend to be selected in response to fluvial geomorphic processes, which, along with hydrology, force a more or less predictable template onto the biotic components of the system. According to the RCC, the kinds of producers, consumers, magnitude of organic inputs, and degree of heterotrophy or autotrophy should be predictable along the physical gradient. Ecological communities should be in dynamic equilibrium with the stream, and the openness of streams, connecting upstream and downstream processes, is manifested in the RCC.

Figure 2 depicts the RCC. The first thing that can be seen is that the stream is organized as a gradient, from an idealized headwater stream to a large river (stream order is on the left of the diagram, and it suggests a logarithmic scale). The figure also attempts to unify biological communities with functional and ecosystem-level properties.

The RCC authors divide streams into headwaters (orders 1–3), medium-sized streams (4–6th order), and large (>6th order). They point out that many headwater streams are dominated, in terms of the energy coming in, by the allochthonous inputs from out of channel, because the tree canopy tends to close off the stream from direct sunlight. In this case, the *P:R* ratio (the ratio of primary production to ecosystem respiration) is less than 1, and most of what enters the stream is coarse particulate organic matter (CPOM, matter > 1 mm), which, in the case of tree boles, can be very coarse indeed. The aquatic food chain here is dominated by organisms that can deal with CPOM, mediated by microbial processing – the so-called guilds of shredder, grazers, collectors, and their predators.

Moving downstream, the relative contribution from allochthonous inputs declines, and autochthonous production (from submersed macrophytes, phytoplankton, and epiphytes) and processed inputs from upstream (now fine particulate organic matter (FPOM), 0.005–1 mm grain size) become more important. Somewhere in this mid-zone, *P:R*

Figure 2 The River Continuum Concept. Reproduced from Cummins KW, Cushing CE, and Minshall GW (1995) Introduction: An overview of stream communities. In: Cushing CE, Cummins KW, and Minshall GW (eds.) *Ecosystems of the World, Vol. 22: River and Stream Ecosystems*, pp. 1–8. Amsterdam, The Netherlands: Elsevier.

reaches a maximum and is greater than 1, indicating that this is the most productive (*in situ*) part of the continuum.

The large river end of the gradient is dominated by FPOM inputs and primary production, but the latter can be limited due to turbidity (due in part to inorganic sediment, not discussed explicitly in the RCC). Turbidity attenuates the light in the water column; thus, phytoplankton production may be limited and P/R is predicted to decrease. Because large rivers increase in depth, they become more lake-like, with a deep

water column and a muddy benthic zone, so that many of the stream insects drop out of the system.

The RCC also makes predictions about where in the system the maximum diversity of organisms should occur (in the medium-sized reaches, or areas with high physical variation, because these are arguably the most diverse of habitats), and that the biotic components of the system will serve to enhance the stability of the ecosystem (referring to a long-ongoing debate as to the importance of biodiversity to ecosystem stability).

One final prediction, or observation, in the RCC is that rivers have both spatially and temporally redundant groups of organisms that tend to perform the same kinds of ecosystem functions, that is, breaking down the organic matter inputs and remineralizing nutrients; they also argue that one should not expect to see the development of successional stages of biotic communities in rivers, "...because the communities in each reach have a continuous heritage rather than an isolated temporal composition within a sequence of discrete successional stages (Vannote *et al.*, 1980, p. 135)." We shall see later on, that scientists dispute this idea.

Resource (Nutrient) Spiraling

All land represents a downhill flow of nutrients from the hills to the sea. This flow has a rolling motion. Plants and animals suck nutrients out of the soil and air and pump them upward through the food chains; the gravity of death spills them back into the soil and air. Mineral nutrients, between their successive trips through this circuit, tend to be washed downhill. Without the impounding action of soils and lakes, plants and animals would have to follow their salts to the coast line. (Leopold, 1941.)

The famous conservationist, Leopold, makes important points in his elegant prose: First, there is a tendency for elements to run downhill from the uplifted land to the sea, and second, that biota play a key role in slowing down this transfer. Third, he speaks of the rolling motion of mineral transfer across the land and waterscape. Webster (1975) used the term spiraling to describe the combined downhill movement and cycling aspects of nutrients and organic matter, and Elwood *et al.* (1983) derive a specific model to describe the dynamics. The concept describes how an atom of a resource (a nutrient like N, P, or C) moves into a stream and how it is retained, processed, and released downstream. The atom may travel downstream, be picked up in a part of the system, cycled there many times, buried for some time, or released relatively quickly. The spiraling model provides an analytic framework to quantify the relationships between biogeochemical processing of materials and hydrodynamic transport, proposing the spiraling length as a measurable index of this interaction.

Spiraling of nutrients in streams is slowed by biotic retention (through sorption and ingestion) of dissolved and particulate forms. Recycling of nutrients *in situ* further slows

	Mechanism		Effect on nutrient cycling		Ecosystem response to nutrient addition	Ecosystem stability	Categorization of study streams
	Retention	Biological activity	Rate of recycling	Distance between spiral loops			
(a)	High	High	Fast Cycling rate > 1	Short 	Conservative ($I > E$)	High	MI 2,3 PA 1,2,3
(b)	High	Low	Slow	Short 	Storing ($I > E$)	High	OR 1,2 ID 1 MI 1
(c)	Low	High	Fast	Long 	Intermediately conservative ($< A$ but $> D$)	Low	ID 3 MI 4 PA 4
(d)	Low	Low	Slow	Long 	Exporting ($I = E$)	Low	OR 3,4 ID 2,4

Figure 3 Predicted effects of interactions of downstream transport and measures of biological activity, and postulated responses of the river ecosystem to disturbance, here in the form of nutrient addition. I, import; E, export. The last column refers to streams in a study (by state) and their approximate stream order. From Minshall (1983), reproduced in Cummins KW, Cushing CE, and Minshall GW (1995) Introduction: An overview of stream communities. In: Cushing CE, Cummins KW, and Minshall GW (eds.) *Ecosystems of the World, Vol. 22: River and Stream Ecosystems*, pp. 1–8. Amsterdam, The Netherlands: Elsevier.

down their downstream transport. Adopting a steady-state, averaged approach for a first derivation, the total downstream flux of a nutrient (F_T) is related to the standing stock of nutrient available per unit length of stream (N) and the average downstream travel speed (velocity) of the nutrient (v):

$$F_T(g\ s^{-1}) = N(g\ m^{-1}) \cdot v(m\ s^{-1})$$

As the biota take up the nutrient (postulated to occur mostly on the stream bottom), the average downstream velocity of the nutrient slows. The channel waters are assumed to be highly advective and the channel bottom retentive.

A second aspect of spiraling is the rate at which nutrients are cycled in the stream. The use rate of a nutrient N is defined as

$$U(\text{use rate, } g\ m^{-1}\ s^{-1}) = k(s^{-1}) \cdot N(g\ m^{-1})$$

where k is a constant of proportionality (the fraction of the standing stock of N that is recycled per unit time, time being seconds in this case). A nutrient atom on average completes a cycle in $T = 1/k$.

By dividing the first equation by the second one, a ratio of retention to cycling is obtained:

$$Nv/Nk = v/k = vT = F_T/U = S$$

$$(m\ s^{-1})/s^{-1} = (m\ s^{-1})s = (g\ s^{-1})(g\ m^{-1}\ s^{-1}) = (m)$$

The parameter S is the average downstream distance traveled by a nutrient atom during a cycle (between bottom and flowing water) and is called the spiraling length. If the value of k is large (high cycling rate within the stream section) and v is low (resistance to stream transport), then S will be short and a greater retention of the nutrient is implied.

Figure 3 illustrates several predictions for how the spiraling length will be affected by different retention and biological processing rates. Ecosystem stability and response to nutrient loading (a disturbance) are also predicted as a consequence of spiraling.

The nutrient spiraling model can be elaborated for any number of compartments, and different nutrient spirals can be measured simultaneously as well. Carbon is one exception that is treated separately, because carbon moves so readily in and out of the dissolved and gaseous phases.

Another important point about spiraling is the potential to identify fast and slow components of the system. Slow components (with tight nutrient spirals and short S) are postulated to be relatively resistant to perturbation, implying that these help to stabilize a system in the face of disturbance.

Serial Discontinuity Concept

This heuristic model is a corollary to the RCC, developed by two river scientists (Ward and Stanford, 1983) from the Western US, where many rivers do not flow freely. Whereas the RCC is intended to describe more or less pristine systems, Ward and Stanford were concerned about rivers that contain dams and impoundments. They argued that such regulating structures reset the river continuum, although not always in the low-order to high-order direction. The key feature of serial discontinuity is that it can cause a stream reach to behave or

Figure 4 Main features of the Serial Discontinuity Concept, describing the effect of an impoundment on a river ecosystem. DD, discontinuity distance is the distance that a parameter is displaced; PI, parameter intensity, or degree to which a parameter is altered (Ward and Stanford, 1983).

function like reaches that the RCC would predict should occur in a different stream order. **Figure 4** illustrates the general concept.

The serial discontinuity concept proposes that in regulated rivers, two measurable parameters of interest are the discontinuity distance (i.e., how far up or downstream a given stream parameter becomes displaced) and the parameter intensity (how much has the maximum value, duration, etc. of the parameter been changed).

Flood Pulse Concept

In contrast to the RCC, which predicts a downstream decreasing influence of the riparian zone, the flood pulse concept (Junk *et al.*, 1989; Junk and Wantzen, 2004) deals with rivers that interact strongly with the floodplain by rising out of the channel bed. This theory describes the effect of floods on river channel and floodplain in large, unregulated rivers of this type, and thereby incorporates a lateral dimension in the consideration of ecosystem structure and function.

During nonflood periods (see **Figure 5**), the floodplain (which is functionally similar to a large wetland) develops and maintains its own nutrient cycles, and depending on the geomorphic configuration of the floodplain, matter may accumulate in place or enter the stream as described in other models. The pulse of a seasonal flood causes the stream to push out, sending nutrients and river biota over the floodplain. If such a pulse is predictable, then communities of organisms will evolve to take advantage of the pulse because it amplifies resource availability. The flood pulse is postulated to enhance diversity and productivity by structuring the dynamics of plants, nutrients, detritus, and sediments.

During floods, matter that was remineralized in the floodplain is quickly dissolved and made available to aquatic primary producers and production in many of these systems (including the Amazon; Bayley, 1995) exceeds decomposition. As the floodwaters stop rising, decomposition in deeper, slower moving parts of the stream increases, often becoming

Figure 5 Schematic of the Flood-Pulse Concept. Reproduced from Bayley PB (1995) Understanding large river-floodplain ecosystems. *BioScience* 45: 153–158, with permission from AIBS.

anoxic. Terrestrial plants, in the meantime, shift into the sites of retreating waters and begin to build up terrestrial biomass again.

The moving littoral zone is used by many fish as a nursery for young and by aquatic invertebrates that can utilize shallow environments. Many fish have adapted to the pulse by

spawning just before the floods so that their offspring can be on hand when the pulse triggers off the high primary production with associated high secondary production. A useful paradigm in the tropics, it is thought that this kind of floodplain–river dynamic was also common in temperate ecosystems before extensive human alterations occurred.

Figure 6 Diagram of the Telescoping Ecosystem Model. Reproduced from Fisher SG, Grimm NB, Marti E, Holmes RM, and Jones Jr. JB (1998) Material spiraling in stream corridors: A telescoping ecosystem model. *Ecosystems* 1: 19–34. The cylinders represent different zones of the system. See text for explanation.

Telescoping Ecosystem Model (TEM)

Fisher *et al.* (1998) presents another way of looking at the holistic, biogeochemical functioning of river systems and their environs, and bears some discussion. In contrast to the RCC that visualizes riverine systems as continua, and in contrast to models such as nutrient spiraling, which assumes rivers are simple, uniform chemostats, these authors emphasize heterogeneities in space and time:

*The landscape is a patchwork of many patch sizes and shapes. Materials follow a large number of routes from uplands to oceans. The path is stochastic and often downhill because the predominant transporting vehicle is water. Because these hydrologic linkages are driven by weather, the path is episodic and jerky. Within patches, characteristic rates of uptake, transformation, and release occur: thus, as the vehicle (water) travels, its load (elements) is adjusted in response to patch-specific material dynamics. (Fisher *et al.*, 1998, p. 20.)*

This perspective corresponds to the understanding of variable source flow in watershed hydrology and takes into account the patchiness and position of patches in the landscape.

As connectors of landforms with lakes and oceans, rivers with relatively fast throughput link land and water units with considerably larger residence times; thus, the connection of land–river–lake or land–river–ocean is (to some extent) slow–fast–slow in terms of biogeochemical movements or high–low–high in terms of retention. Because of the difference in time constants among these units of the landscape, Fisher *et al.* (1998) focus on the landscape factors that influence the ability of rivers to retain matter.

River systems are composed not only of the surface flow channel, but also of several adjacent parts (see Figure 6). The stream is embedded in a saturated zone called the hyporheic (underneath the flow) zone and around this is a zone often seen as gravel bars at the surface, with underlying saturated sediments termed the parafluvial. The riparian (bank side) zone beyond this forms a larger buffer between the stream and

upland areas and also overlies saturated soils. These zones are often readily distinguishable, particularly in arid landscapes. Fisher *et al.* (1998) term the spatially explicit arrangement of these units as the configuration of the system, and this can affect the rates of transfer, uptake, processing, and release of materials.

Similar to the spiraling length index developed by Webster (1975) and elaborated on by Elwood *et al.* (1983), Fisher *et al.* define a parameter they call the processing length or the length of subsystem required for biogeochemical transformation of some substance (note that this is left intentionally vague). The key element that is different about processing length versus spiraling length is that the former applies to all these zones (stream channel, hyporheic, parafluvial, and riparian) and that these characteristic processing lengths are expected to be quite different. For example, the NO_3 concentration in the authors' study stream, Sycamore Creek in Arizona, is controlled by algal uptake rate (the predominating *N*-transforming process), with a processing length of 42 m. In the parafluvial zone, nitrate is controlled by nitrification (due to microbial decomposition) and has a shorter processing length of 13 m.

The RCC posits that classical ecological succession does not occur in river systems, because the physical constraints dominate the development of ecological communities. Fisher and colleagues, who work in desert ecosystems where rains are infrequent and episodic, view river systems as going through succession, with processing lengths becoming shorter over time, until an episodic disturbance (flood, fire, dumping toxicants) resets the system.

Fisher *et al.* (1998) liken their observation of stream system zonation, and the dynamic differences in processing lengths within each, to the cylinders of a telescope (hence the model name). In particular, with respect to disturbance, they hypothesize that

1. When a stream system is disturbed, the different subsystems will alter their processing lengths, but differently. The resistance of the system, or how little it changes when

perturbed, is inversely proportional to processing length change and will be greatest away from the center of the telescope; and

2. The resilience of the stream telescope (how fast the system returns to the previous state) decreases away from the center.

These two emergent properties of the TEM are shown in **Figure 6**. However, cross-links (interactions between the sub-systems) are proposed to enhance the resilience of the system. Thus, the TEM is a model that can not only predict the rates of system change, but also maintains a hierarchical structure.

Riverine Ecosystem Synthesis (RES)

Similar to the TEM is the RES proposed by Thorp *et al.* (2006). An attempt to synthesize and generalize the multitude of lotic paradigms, the RES identifies hydrogeomorphic patches – places where flows and geomorphology produce particular characteristics – that are arrayed throughout catchments and drive ecosystem dynamics. The RES emphasizes the importance of connectivity to terrestrial parts of catchments as well as temporal influences.

Geomorphic–Trophic Hypothesis and Other Geomorphological Controls on Ecology

Recent work in relatively undisturbed ecosystems has demonstrated how topography and landscape position can influence not only the biogeochemistry of waters within a catchment, but also the invasibility of aquatic habitats by organisms, which sets the stage for subsequent ecological interactions. At a Long-Term Ecological Research (LTER) site in northern Alaska, researchers found that the fish communities of lakes, connected by streams, are determined by such factors as basin steepness (which determines waterfalls that may not be passable by certain fish species), lake depth and size, etc. (Hershey *et al.*, 1999). This results in a limited number of fish communities, and the species present appear to regulate the presence and abundance of other organisms (invertebrates and phytoplankton). Within this simple, Arctic ecosystem, the geomorphic–trophy hypothesis provides an insight into how ecological communities develop, and in particular, how basin geomorphology can constrain the mix of species. These mechanisms likely are at play in many high-elevation systems that are relatively undisturbed. Even if natural manifestations of this hypothesis may be difficult to observe in systems subject to human alteration, the fact that rivers are engineered in various ways does, in fact, promote some of the predictions of this hypothesis.

Riverine Biota

Microbiota

Microbiota are widely recognized as being the most abundant and diverse organisms on earth. One cubic centimeter of water can hold more than 10^9 bacteria. Microbes are responsible for most of the biogeochemical processing of nutrients and

organic matter in rivers. Some important functional groups of bacteria are nitrifiers (which convert organic N into nitrate and nitrite), the denitrifiers (which convert nitrate and nitrite back into atmospheric N), sulfate reducers, and methanogens (which convert carbohydrates into methane). Microbes can be free-swimming or attached to particles; they are found in the hyporheic and riparian zones as well as in the water column itself. Microbial diversity, although recognized as vast, is difficult to assess, but new techniques involving DNA are improving the process of identification and classification.

Plants

Riverine plants fall into two general groups: the littoral, mostly rooted vegetation (macrophytes or literally, large plants), and the microscopic, free-living phytoplankton as well as attached microalgae. Macrophytes can be further divided into those that send their leaves up above the water surface (emergent macrophytes) and those that photosynthesize within the water column (submersed macrophytes). A number of macrophytes are also free-floating, such as the water hyacinth (*Eichornia crassipes*), which has enlarged, buoyant leaf stems. A number of algal species are also macrophytic.

Aquatic vascular plants have a number of special adaptations for dealing with the conditions imposed by the aquatic environment. Many plants have roots that extend into the water-saturated sediments, and as a result, are faced with an anoxic environment. To avoid root anoxia, many species have evolved air spaces (aerenchyma) in their roots and shoots that conduct oxygen down from the leaves. An example is the American water celery (*Vallisneria americana*), which translocates so much oxygen to its roots that it actually oxidizes the surrounding sediments, which in turn causes iron to precipitate and form concretions of iron oxides on the roots.

Macrophytes that grow in the brackish or salty parts of rivers have more fresh water within their cells than in the surrounding water; thus, the osmotic concentration gradient tends to force water out of the plant into the water. To avoid dehydration in this manner, vascular plants have a number of adaptations for maintaining their osmotic balance, including specialized cells that either serve as barriers to salt intrusion or glands that actively excrete salt. In mangroves (*Rhizophora* spp., *Avicennia* spp.), for example, the root endodermis is highly salt resistant and serves as a salt filter, and leaf cell membranes also serve as filters by excluding sodium and selectively transporting potassium. The emergent salt-marsh plant, *Spartina*, excretes salt crystals from specialized glands in its leaves.

Phytoplankton, the microscopic plants that float in the water column, rely on turbulent flow to remain high enough in the water column to photosynthesize. In this photic zone, phytoplankton can fix carbon and reproduce, but below this zone, they can only respire away their carbon. In shallow rivers, this is usually not a problem, as the entire water column may be photic, but larger rivers usually become turbid due to the downstream transport of sediments, organic detritus, etc.

The main groups of phytoplankton are the green algae (colonial greens, diatoms, desmids, and others), blue-green algae or cyanobacteria, and dinoflagellates (which are actually both autotrophic and heterotrophic). Diatoms have hard

exteriors, called frustules, which are composed of silicate; thus, they cannot persist if this mineral is in short supply. They are an important taxonomic group in rivers, and often, the riverine populations are maintained by inputs from the tributaries. Algae in small streams often grow directly on rocks (epilithic algae) and can be an important source of organic matter in open (not covered by tree canopy) river segments. A number of microalgae, including diatoms, can grow on the surfaces of attached plants. These may be disproportionately important in riverine food webs. Blue-green algae, such as *Anabaena* or *Oscillatoria*, can fix N from the atmosphere by means of specialized cells called *heterocysts*; they will do this if there is an excess of available P, such as from cultural eutrophication.

Macrophytic algae are attached to hard substrates and are common in streams or along the littoral zones of larger rivers. Some, such as *Cladophora*, grow as filaments, whereas others (*Ulothrix*, *Oedogonium*) grow in tufts; *Chara* and *Nitella* are branched and their cell walls are reinforced with calcium carbonate. The filamentous green alga *Cladophora glomerata* is a cosmopolitan species that does particularly well in the presence of elevated nutrients, and therefore, large colonies serve as bellwethers of cultural eutrophication.

In a review of phytoplankton diversity from 67 rivers around the world, Rojo *et al.* (1994) found that the average species richness was 126, and about half of the species were reported as sporadic. The average species richness was higher in temperate rivers (130 species) than in the tropics (75 species). The total numbers of species enumerated, by family and zone, are given in Table 1.

Although the tropical rivers may have been underrepresented in the survey, there are some clear trends. Diatoms are the most diverse taxon and predominate in temperate systems, whereas desmids are of greater importance in tropical rivers.

Invertebrates

The invertebrates that live in rivers can be divided into two groups: the zooplankton (animals that live suspended in the water) and the zoobenthos (animals that live in or on surfaces such as the river bottom, plants, etc.). River currents usually are

much faster than the swimming speeds of the zooplankton; thus, washout downstream is a major problem for river zooplankton. Consequently, zooplankton are common in rivers only where their growth rates (or inputs from nearby lakes and wetlands) exceed loss rates from washout and other losses (e.g., predation). Thus, river zooplankton is usually dominated by rotifers and small cladoceran crustaceans, which have high growth rates. Zooplankton densities often are the highest when the water is warm and low, when the growth rates are high and the washout rates are low. The biomass of zooplankton in the main channel of rivers is usually much lower than that in lakes, but off-channel habitats such as oxbow lakes may support rich zooplankton populations. River zooplankton often includes a few dozen species of rotifers, cladocerans, and copepods, fewer than 10 of which are abundant. At least some of these species probably are sustained by inputs from nearby habitats that are more hospitable to zooplankton, such as backwaters, impoundments, or lakes. Most riverine zooplankton are neither specialized nor endemic: the same species and genera of zooplankton that live in rivers are also common in lakes, and occur in rivers worldwide. Despite its low density and richness, river zooplankton plays an important role as food for young of many species of riverine fish, as well as adults of a few specialized zooplanktivorous fish such as paddlefish, *Polyodon spathula*.

By comparison with the zooplankton, the riverine zoobenthos is often rich and dense. A typical large river contains several hundred species of benthic invertebrates representing a biomass of 1–100 g m⁻² (ash-free dry matter). Dominant groups include insects (chironomid midges and many others), bivalves, prosobranch (gill-breathing) snails, tubificid oligochaetes, and (in tropical rivers) crabs and prawns. As is the case with zooplankton, most of these species are not associated with the open waters of the main channel, but with shorelines, backwaters, vegetation, and other structurally complex habitats along the river margin (Table 2). Unlike the zooplankton, many zoobenthic species are found only in rivers and are endemic to particular river systems. Thus, the rivers of southeastern North America contain several hundred species of mollusks and crayfish that are found neither in American lakes nor in rivers elsewhere in the world. The local density and species composition of riverine zoobenthos are governed by the

Table 1 Species richness of riverine phytoplankton. Temperate and tropical percentages indicate the taxon representation in temperate and tropical planktonic assemblages, respectively

Family	Total number of species	Temperate (%)	Tropical (%)

nature of the bottom (particle size, organic content, stability), flow conditions (current speed, frequency, and size of floods and droughts), the availability of food supplied by phytoplankton, rooted vegetation, attached algae, and the watershed, and biological interactions such as predation and competition. According to the River Continuum Concept, large rivers should be dominated by filter-feeding animals (both benthic and planktonic) and burrowing deposit-feeders. Data to test this idea in large rivers have not been collected, but it appears that large rivers actually contain a rich variety of feeding types, including filter-feeders, deposit-feeders, predators, algal scrapers, and herbivores that eat rooted plants.

Like the zooplankton, the zoobenthos is an important source of food for riverine fishes. Insects and crustaceans appear to be especially important as fish food, perhaps because many species are active and live above the sediment–water interface, where they are accessible to fish. Benthic filter-feeders (especially bivalves) are sometimes so abundant that they control the number and kind of phytoplankton and other suspended particles in rivers. Through their burrowing and feeding activities, benthic animals may also affect sediment mixing and the exchange of substances (e.g., nutrients, toxins) across the sediment–water interface. Also, humans use riverine invertebrates as food (e.g., prawns, crabs, crayfish, mussels, oysters), bait (crayfish, large insects), or ornament (e.g., pearly mussels, whose shells and pearls have been collected for thousands of years).

Human alteration of the hydrology of large rivers, introduction of toxins and exotic species, and destruction and isolation of the lateral habitats that are important to both zooplankton and zoobenthos have had strong effects on the biodiversity and function of riverine invertebrates. Because of their considerably greater degree of habitat specialization and endemism, the large-river zoobenthos has been affected more severely than the zooplankton, with hundreds to thousands of species now extinct or endangered.

Fish

Fish compose more than half the known species of vertebrates. At present, around 29,000 valid species of fish have been described, but the actual number is likely closer to 32,000 (Nelson, 2006; Froese and Pauly, 2011). Of these, approximately 12,000 species live strictly in fresh water and another 500 species use freshwater habitats over some part of the life cycle (recall that fresh water composes only 1% of the world's water!). Many of the freshwater resident species, and all of the occasionals, use rivers for part or all of their lives.

Riverine fish faunas can be very depauperate, as in small, oligotrophic headwater streams, or they can be highly diverse as in many large, tropical rivers. Fish occupy virtually every heterotrophic ecological niche, from parasite to detritus-feeder, to herbivore, planktivore, insectivore, and piscivore (fish-eater). Large, predatory fish can also consume other organisms, such as small mammals, herps, and birds. In the tropics, where seasonal floods cause rivers to spread out over the floodplain (*see* Flood Pulse Concept, above), many fish species time their reproduction just before the floods, so that

their offspring use the flooded forests as nursery habitat. Many tropical species also directly consume leaves, fruits, and seeds while foraging in the flooded forest.

Riverine fish species are adapted to flow regimes that are considerably more turbulent than lakes or oceans. In the riffles and rapids of lower order streams, many fish spend much of their time in patches of quiet waters, such as under rocks, behind boulders or tree roots, or along the riparian banks, emerging briefly to feed. The larvae of freshwater lamprey (ammocoetes) actually live under the stream, in the hyporheic zone, for up to six years. In higher order streams, current velocities are slower, and fish may swim more freely in the water column. An exception is in tidal estuaries, where currents at peak flood and ebb may be as high as a meter per second or more. Some fish apparently ride the tides selectively, entering a tidal current to move either up- or downstream, and then moving out of the flow to remain in place. This may be a common strategy for the fragile larvae to move upstream in tidal rivers (*cf.* Morgan, 2006).

A fairly small, but important, group of fish undertakes large-scale migrations between fresh and marine waters. These so-called diadromous fish number about 200 species, most of which are anadromous or freshwater-spawning. This group includes many of the salmon, the southern-hemisphere galaxiids, and many herrings. These species use the freshwater environment to spawn; the young rear in the relatively protected riverine or estuarine environment and subsequently migrate to sea to feed, grow, and mature. A few species, notably the freshwater eels (Anguillidae), have the opposite strategy (catadromy), spawning at sea and then moving into fresh water to mature. Diadromous fish are important in many fisheries, as their spawning migrations tend to concentrate their numbers and make them relatively easy to catch. Unfortunately, this group of fish is under a multitude of threats from overfishing, habitat loss or alteration, and pollution. In the North Atlantic basin, of the 22 major species, all but one (striped bass, *Morone saxatilis*) have declined severely and one (the houting, *Coregonus oxyrinchus*) was recently declared extinct (Limburg and Waldman, 2009).

Studies of riverine fish diversity on a global scale reveal that species richness increases with the size of the drainage basin and with river discharge (note – discharge and drainage size are closely correlated in unimpounded rivers). Tropical rivers also tend to be more speciose, and this is in part due to warmer water temperatures, which stimulate primary productivity (Figure 7). The Amazon River, being both the largest river and tropical, supports close to 4000 species. Some of the high-diversity groups in tropical rivers include the catfishes (Siluriformes), the minnows (Cypriniformes), and characins (Characiformes).

Other large animals

Although the numbers of other animal species that use rivers are far smaller, they can be important components of these ecosystems. Among the amphibians and reptiles are frogs and water snakes, many turtles, and the Crocodylia (alligators, crocodiles, and allies). Shoreline bird species are numerous, including herons, ibises, cranes, and top predators such as eagles and ospreys. Mammals, such as beaver (*Castor* spp.),

Figure 7 Patterns of riverine fish species richness, as functions of (a) drainage basin size, (b) mean annual river discharge, and (c) latitude. Note the log scales. Reproduced from Oberdorff T, Guoigan J-F, and Hugueny B (1995) Global scale patterns of fish species richness in rivers. *Ecography* 18: 345–352.

otter (*Lutra* spp.), and hippopotamus (*Hippopotamus amphibius*), function as keystone species in many systems, either by virtue of their physical alteration of the habitat (beavers, hippos) or trophic influence (otters). Beavers build dams, which create ponds that alter the flow characteristics, and hence the processing of organic matter, in small- to medium-sized (first to fifth order) streams in North America and Europe. Hippos, by creating aquatic highways between their daytime resting areas and night-time foraging grounds, can cause drainage alterations that can be seen in satellite imagery (McCarthy *et al.*, 1998). Some tropical Asian rivers support freshwater dolphins and sharks. Further, many large mammals, including many of the threatened or endangered “charismatic megafauna,” occur in riparian zones of rivers; for example, flooded tropical grasslands are an important riparian habitat for such animals.

Threats to Biodiversity

Humans have always modified rivers and their watersheds, both deliberately and inadvertently. Human settlement and development transforms the landscape from its natural patterns of vegetative cover to networks of roads, drainage works, farms, and urban areas aimed at efficient transportation, food production, and sanitation. In the last century, technological advances have enabled the transformation of the landscape on an unprecedented scale. The effects of human activities now even threaten to modify climatic factors. The effects of these transformations on the resident species of the watershed have been underestimated in the past, largely due to ignorance. Table 3 reviews some examples of the effects of human activities on riverine ecosystems.

Dams

In many areas, dams are constructed for flood control, water supply, and hydroelectricity. To keep up with world demand for water and energy, dams are being constructed at an unprecedented rate. Approximately 40,000 large dams have been constructed in the past 50 years, and the total area of land flooded by large dams exceeds 4,00,000 km² – an area the size of California. In the US alone, there are nearly 20,00,000 small dams and 68,000 dams two stories (6 m) or higher. Additionally, many other small structures (e.g., culverts) disrupt biological connectivity as well.

The most obvious ecological effect of a dam is to act as a barrier to water flowing downstream. Sediments are no longer transported downstream, but rather accumulate behind the dam. For example, before the construction of the Aswan Dam in the 1960s, the Nile River in Egypt transported more than 120 million tons of sediment to the Mediterranean annually, and 10 million tons were dispersed in the floodplain and delta, providing fertile soils that were farmed for millennia. The dam now retains 98% of the sediments, which cut off the vital mechanism of soil renewal, causing a decline in floodplain agriculture and also resulting in coastal erosion.

In ecological terms, a dam is a most effective barrier for migrating fish and other species, and the presence of dams is known to eliminate or drastically reduce the populations of these species unless mitigating structures (e.g., fish ladders) are put in place. Even these are only partially successful: in many rivers with hydroelectric dams, the passage of fish to upstream spawning grounds is a one-way ride, for most of these fish are killed as they attempt to move downstream and pass through the turbines. In large rivers with multiple mainstem dams, fishways may also fail because fish cannot negotiate several

Table 3 Threats to biodiversity in rivers

Human impact	Proximate effects	Consequent short-term change in		
		Productivity	Dominant species	Species richness
Damming	Reduction and change in temporal patterns of flow, sediment flux, turbidity	Decreases downstream associated with nutrient reduction	Shifts associated with changes in nutrient ratios (e.g., N : P, Si : N), flow reduction, and barriers to migration	Probable decline, particularly in migratory species
Stream channelization	Increase in flow velocity; disruption of benthos, hyporheic zone	?	Species shifts associated with altered flow regime	?
Nutrient loading	Fertilization of productivity; fueling of increased respiration	Increase in GPP, respiration; BOD	Species shifts associated with changes in nutrient ratios, oxygen levels	Declines associated with anoxia; potential collapse of some communities
Toxic substance loading (heavy metals, pesticides, toxic organics)	Increased mortality of resident species; reproductive failure	Probable reduction in productivity in response to toxicity	Shifts to tolerant species	Probable short-term decline, but possible long-term increase
Introductions of alien species	Colonization of ecosystem by new competitors	?	Potentially dramatic shifts if the introduction is successful	Potentially dramatic decreases as the new species become established
Land use change (logging, agriculture, urbanization)	Typically, increased sediment and nutrient load; hydrological alterations; possible increases in loading of toxics	Probable shift toward heterotrophy in response to nutrient additions and light reductions	Shifts associated with the first four impacts above	Potential decreases associated with the first four impacts above
Overharvesting of species	Depletion of target species; perturbations in predator and prey populations	?	Shifts to nontarget species; other food-chain-dependent shifts	?
Climate change	Changes in temperature, precipitation, evaporation, and atmospheric CO ₂	Increases or decreases, depending on the location	?	?

BOD, Biological oxygen demand. GPP, Gross primary production.

dams to reach spawning grounds. Many fishways are also inappropriately designed to pass certain species, such as sturgeons and eels.

Less obvious is the effect of dams on flow regime and biogeochemistry. Dams alter the temporal pattern of river discharge as well as the flow pattern of groundwater. Nutrient and sediment fluxes are typically diminished downstream because of settling or biological uptake in the impoundment. The resulting changes in elemental ratios (e.g., the decrease in available silicate compared with N and P; [Humborg et al., 2000](#)) downstream have been associated with species shifts, reductions in productivity, and decreased yields in the downstream fishery.

Stream Channelization and Interbasin Connection

Stream channelization is designed to improve the navigability of rivers or to reduce the flooding potential in streams. In the

former case, the river channel is deepened and widened by dredging, which destroys the benthic habitat. In the latter, the streambed is sometimes straightened and paved to increase the capacity of the stream to transport water downstream. These processes alter the flow regime of the stream, favoring species that tolerate faster, turbulent currents, and excluding others. Changes to the streambed can affect the conductivity of water through the hyporheic zone, which affects nutrient processing (*see* Different Conceptual Models of Riverine Ecosystems).

Additionally, many waterways have been engineered to enhance transportation and trade. Such activities have been undertaken for millennia, such that many alterations have become part of the cultural landscape and heritage. The Mississippi River is a case example, where locks permit barges to change elevation and canalways connect across basins. Similarly, the Saint Lawrence Seaway raised water levels above the natural rapids so that commercial shipping vessels could travel

from the ocean into the Great Lakes. The effects in both systems have included habitat loss, ecosystem alteration, major changes in the hydrograph, and species invasions (*see* Nutrient Loading).

Damming for water supply purposes (*see* Dams) can also result in interbasin transfers of water, nutrients, and biota. In periods of high water demand, which often coincide with periods of low water in rivers, riverine water withdrawal or detention and transfer to municipal water supply networks or irrigation systems can significantly modify flow regimes. For example, the New York City water reservoir system relies in part on dams in the Upper Delaware basin, effectively transferring water from the Delaware to the Lower Hudson River basin via the City's distribution network. In China, the South–North Water Transfer Project is the largest water-works project ever developed there. Plans are to transfer nearly $45 \times 10^9 \text{ m}^3$ of water annually from the Yangtze River in the south to the Yellow River via several routes. This will result in massive changes in water supply, habitat, and fisheries, and will affect communities both downstream and in headwater areas (i.e., across international borders).

Nutrient Loading

As discussed above (*see* Energy and Matter Transformation (Biogeochemistry)), nutrient loading fuels the ecosystem. Excessive loading results in a catastrophic collapse when the resulting increase in metabolism exceeds the available oxygen supply of the river. Cultural eutrophication of rivers is severe to dire in some parts of the developing world, in particular in India, Southeast Asia, and Africa, as well as around many urban centers worldwide. Eutrophication of major watersheds such as the Mississippi draining into the Gulf of Mexico, the Scheldt and the Rhine draining to the North Sea, California's Sacramento River draining into Suisun Bay, or the many eutrophied rivers draining toward the Baltic Sea produce or exacerbate hypoxic or anoxic episodes with increasing frequency.

Toxic Substances

Associated with pesticide application in agriculture (or suburban gardens), industrial effluents, and chemical spills, have a spectrum of effects, all deleterious to organisms. Some herbicides can drastically reduce productivity by direct mortality of aquatic plants. Other chemicals kill sensitive species higher in the food chain. Subtler effects include behavioral changes (due to endocrine-disrupting compounds) in predators or prey species, which can shift the structure of food chains, increase susceptibility to disease, and cause infertility. What complicates this story is that different organisms do not respond uniformly to exposure to a particular toxic substance, so that the effect on a particular riverine system is determined largely by the mix of species present. Chronic exposure to a stream of toxic material will gradually shift the species present to those that can tolerate it, generally resulting in a decline in species richness.

Overharvesting Species

In addition to humanity's indirect impacts on biota, humans threaten biodiversity directly through the overharvesting of

species. In the US and Canada, a number of river-associated fisheries are currently on the decline, including those for several species of Pacific salmon, Atlantic salmon, American shad, sturgeons, eels, and oysters. Worldwide, fishing pressures in rivers are enormous. Many river fisheries in developing countries are artisanal, providing food for a local community, and little is known about harvesting pressures. However, responses of fish communities to overharvesting are becoming understood. For instance, in one West African river, catch per unit of fishing effort remained relatively constant from the 1950s through the 1990s, but the trophic structure of the harvested fish altered from large piscivores to small planktivores, with loss of food web complexity (Figure 8; Welcomme, 1999). This phenomenon is called fishing down food webs, and was first noted in marine fisheries (Pauly *et al.*, 1998). At the population level, overharvesting often selectively removes older age classes, pushing the age of first reproduction down, and often skews the sex ratios in the population (e.g., female sturgeon are selectively sought for their roe from which caviar is produced).

Introduced Species

Humans are also introducing new species into ecosystems at an unprecedented rate. Some of these introductions are intentional: for example, salmon, trout, and bass are stocked into rivers and lakes all around the world for sport fishing, and grass carp are introduced to control aquatic weeds. Many introductions are unintentional, arising from the pumping out of ballast water in large tankers, overland transfer of boats with attached organisms from one drainage to another, or accidental spills. Although most organisms that are introduced into a novel environment perish, the increase in commercial boat traffic particularly increases the likelihood of a successful introduction.

The rates of exotic species introductions are difficult to quantify, in part because many of the species are too small to notice. However, Mills *et al.* (1996) documented the rate of species introductions into the Hudson River, in New York State; since 1840, the rate has been about one successful introduction per year – much higher than natural rates of species flow.

Direct perturbations of the mix of species, either by introduction of new species, or removal of extant species by overharvesting, may cause drastic changes in the relations of the food web, thereby also affecting predators and prey. Some species additions affect their physical and chemical environment as well: in North America, zebra mussels, which were introduced into the Great Lakes in 1988 and spread rapidly through the Mississippi and eastern drainages, have been documented to increase the clarity of the water column by virtue of their filter feeding, and also carpet large areas of the benthos, where they have successfully colonized.

Assessment and Management

River ecosystems are clearly important and are at risk. Their direct economic importance to societies includes their use in transportation, water supply, energy, provision of harvestable products, and they are of cultural and spiritual importance. Their indirect importance, sometimes termed

Figure 8 Example of a fished-down riverine food web, Oueme River, West Africa. Diagram shows how fish catches changed from larger fish to smaller and smaller target species over time. Fish colored in black disappeared before 1965, grey are fish whose numbers were seriously reduced. Arrows indicate species which reduced the age at first reproduction. Note that overall catch per unit of effort remained largely constant. Reproduced from Welcomme RL (1999) A review of a model for qualitative evaluation of exploitation levels in multi-species fisheries. *Fisheries Management and Ecology* 6: 1–19, with permission from Wiley.

essential ecosystem services, includes their fundamental role as biogeochemical transformers of energy and matter, physical transformers of the landscape (shaping the land through fluvial processes), and the provision of a wide variety of ecological habitats along the river continuum.

Historically, the assessment of river ecosystems was hindered by two factors. First, on a practical basis, it is difficult to adopt a single methodology to assess the state of a large river system from headwaters to the mouth. Many of the methods that were developed for small stream study cannot be easily adapted for the higher-order parts of the system, and at the other end of the continuum, oceanographic methodologies may be designed for scales of study that are larger than rivers. Second, until the development of scale-spanning river paradigms such as the River Continuum Concept, ecological

studies of rivers tended to consider a river in isolation from its watershed, but as is now widely recognized, upstream processes in the watershed (including human-accelerated land-use change) have major downstream effects on rivers. (A third difficulty may be due to the somewhat arbitrary tendency of researchers to specialize on broadly different parts of the system: there are many more small-stream and estuarine scientists than there are river scientists.)

The revival of the concept of ecosystem health has proven to be a useful point of departure for the current study and management of river ecosystems (see, e.g., Karr and Chu, 1999 and Simon, 2003). Metrics of ecological communities, such as those that compose indices of biotic integrity (IBI, see Karr and Chu, 1999), can be combined with in-stream biogeochemical measurements (e.g., processing lengths of critical

chemical cycles, ecosystem metabolism, or food web relationships as identified by tracers), in-stream habitat assessments, and whole-watershed metrics (primarily land use, soils, geology, topography, etc.) to provide an integrated assessment of the status and threats to rivers. An emerging consensus is that assessment and management no longer fall solely in the domain of scientists and managers, but must involve those who share a stake in the management process. This is evident in the growth of watershed management councils, which struggle to deal fairly with the tradeoffs between economic prosperity and sustainability of rivers and lakes in watersheds. The difficulty of finding equitable solutions increases as the scales of political boundaries increase: rivers that share or cross international jurisdictions require a higher level of political cooperation. Maintaining river ecosystems as healthy components of the landscape will be one of the great challenges of the twenty-first century.

Glossary

Hydrophily Underwater pollination developed by most seagrasses and many freshwater angiosperms.

Seagrasses Marine angiosperms, all monocots, able to grow submersed in marine waters, to which they are restricted.

Introduction

Seagrasses are angiosperms restricted to marine life. They encompass a limited (approximately 50; Table 1) set of closely related species which have successfully colonized the coastal areas across the coastal ocean from intertidal areas to depths in excess of 50 m in the clearest waters (Duarte, 1991), except for polar seas, from which they are absent (den Hartog, 1970). Seagrasses often develop vast meadows (Figure 1), which are important seascapes covering approximately $0.6 \times 10^6 \text{ km}^2$ in the ocean (Duarte and Cebrián, 1996) and are responsible for a primary production of approximately $0.60 \text{ Gt C year}^{-1}$ (Duarte and Chiscano, 1999) and 15% of the total net CO_2 uptake by oceanic biota (Duarte and Chiscano, 1999). In addition, seagrasses provide habitat for animals, many of which are economically important or endangered, and also play an important role by stabilizing sediments in coastal areas (Hemminga and Duarte, 2000). Hence, the elucidation of their diversity, its maintenance, and its influence on the functions of seagrasses in the ecosystem are important goals for the sustainable management of these key ecosystems. This article provides a comprehensive view of seagrass diversity by examining the origin and current distribution of seagrasses, the controls on seagrass species and genetic diversity and their functions in the ecosystem, and threats to the sustainability of seagrass biodiversity.

The Origin and Evolution of Seagrasses

Seagrass originated early in the evolution of angiosperms, approximately 100 million years ago, from ancestors that have been hypothesized to be freshwater plants or mangrove- or salt-marsh-like plants. The origin of seagrasses appears to be polyphyletic, and recent analyses based on molecular phylogeny have supported the development of seagrass species from three clades of primitive plants (Les et al., 1997). There are two main hypotheses on the origin of seagrasses. One identifies marsh- or mangrove-like plants as their ancestors (den Hartog 1970), which is supported by the observations that some seagrass species present lignified rhizomes and that two genera present viviparous reproduction, similar to some mangrove taxa. The second hypothesis identifies, on the basis of molecular phylogeny, freshwater plants to be the seagrass ancestors (Les et al., 1997). A freshwater ancestor appears

clearer for the genus *Enhalus* (*Enhalus acoroides*), the only seagrass species without submarine pollination, which has been associated with related freshwater plants (*Vallisneria* sp.), that it resembles in form and pollination mode.

The fossil record of seagrass is very scarce, and has not been very helpful in testing hypotheses on the origin or evolution of seagrasses. The oldest specimens in the record consist of, at most, three genera: *Archeozostera*, believed to be the ancestor to the extant genera *Heterozostera*, *Zostera*, and *Phyllospadix*; *Thalassiocharis*, ancestor to the extant genera *Amphibolis*, *Thalassodendron*, *Halodule*, *Cymodocea*, and *Syringodium*; and *Posidonia*, the only extant genera among the three from the Cretaceous.

Evolution of Seagrasses

Although the path of seagrass evolution is not very clear due to the small size of the fossil record, there is evidence that most modern seagrass genera were already established in the Eocene, but the genera *Phyllospadix* and *Enhalus* appear to have evolved in the Palaeocene. The evolution of seagrasses has been postulated to be linked to the development of four major capacities essential for life in the marine environment: (i) the capacity to grow underwater, (ii) the development of mechanisms to tolerate the high salinity of the sea, (iii) the development of substantial anchoring capacity so as to enable seagrasses to remain attached to the substrate in the high-energy marine environment, and (iv) the capacity for underwater pollination (hydrophily). The net result of the action of these constraints is that seagrasses represent a rather homogeneous plant group: All seagrasses are rhizomatous plants, with basal meristems, generally blade-like leaves, and mostly hydrophilous pollination. These adaptations may have all been present in some of the freshwater plants, particularly those resistant to high salinity, that may have acted as ancestors to the seagrasses. In contrast, the hypothesis of possible marsh or mangrove ancestors would have required the evolution of most of these adaptations. In particular, the capacity to grow underwater relies critically on the development of an extensive lacunar system able to transport gases between the different organs of the plants, thereby supplying photosynthetic oxygen to the roots and, possibly, CO_2 derived from respiration to enhance leaf photosynthesis. This lacunar system may have already been present in possible freshwater ancestors, such as that for *E. acoroides*. Hydrophily, which is

Figure 1 A mixed (seven species) seagrass meadow in Bolinao (Pangasinan, the Philippines).

believed to have played an important role in seagrass evolution, affecting their speciation, was already present in possible freshwater ancestors but must have been evolved independently under the hypothesis of mangrove- or marsh-like ancestors. Although its importance is undisputed, the capacity for underwater pollination is not an essential adaptation to life in the marine environment. For example, *Enhalus*, the most recent seagrass genus, pollinates over the water surface as did its ancestor freshwater plants, and yet it is clearly a successful plant in the Indo-Pacific region. A freshwater ancestor for seagrasses is further coherent with new evidence suggesting that the first angiosperms may have also originated in freshwater environments.

The Seagrass Flora: Species Richness

Seagrass Taxonomy: Status and Uncertainties

The seagrass flora is composed of approximately 50 species, distributed in 12 genera, belonging to only two families from two closely related orders (Table 1). Despite the small number of species, the taxonomy of seagrasses is far from settled, and there is considerable uncertainty not only at the level of species but also at the level of genera. Indeed, the total number of species described could, if uncritically accepted, exceed 60. Although species descriptions are often based on reproductive structures, these characters are, in practice, not always useful as diagnostic criteria to separate them. In practice, the identification of species in field studies is often dependent on vegetative characters to discriminate between genera, whereas the discrimination of species within genera is often based on the biogeographical segregation between species because congeneric species are often present in different floras. The diagnostic characters most commonly used to classify seagrasses into genera and species include differences in the venation, the presence of tannin cells, denticulation, and the tip shape of leaves (den Hartog, 1970). Although differences between reproductive structures are likely to be robust indicators of the broad genetic differences expected from species, differences in leaf anatomy are not as reliable. Leaf characteristics are remarkably plastic within seagrass species, even within adjacent shoots, rendering their diagnostic value

New York: Elsevier.

questionable. Classification systems based on differences in leaf characteristics are therefore conducive to an ever-increasing number of species, particularly in the small and very plastic genus *Halophila*.

It is clear that a major revision of the taxonomy of seagrass species is needed, and that this revision cannot be based on anatomical or morphological characters alone. Experiments to test for phenotypic plasticity and the more parsimonious methods of molecular taxonomy must play a critical role in this revision. The use of biogeographic separation as diagnostic criteria for species and genera is also questionable because the current distribution of seagrasses may result from local extinctions isolating previously continuous distributions. Indeed, populations of some species with a wide distribution are genetically isolated across biogeographical regions (e.g., *Zostera marina*), although there is no evidence that such isolation may have resulted in sufficient genetic changes as to render them different species. In fact, the description of some seagrasses as separate species on the basis of their biogeographic separation (e.g., *Zostera* and *Phyllospadix* species at either side of the Pacific) has yet to be validated by robust genetic analyses. Indeed, examination of seagrass phylogeny using molecular markers has led to the postulation that there is no basis to separate *Zostera* and *Heterozostera* species into different genera (Les *et al.*, 1997) and has generated a new, more parsimonious, tree of genetic relationships between the species (Table 2) that represents a useful departure point for the needed reassessment.

Independently of current uncertainties regarding the exact size of the seagrass flora, it is clear that seagrasses are minor contributors to the richness of plant species in the sea, where they represent <0.5% of the oxygen-evolving photosynthetic species. This minor contribution cannot be accounted for by the comparatively much longer evolutionary history of marine algae because seagrasses also represent <0.02% of the angiosperm flora, despite an early origin in the angiosperm evolution. Although extinctions of some genera are documented in the fossil record, it is unlikely that past seagrass floras ever comprised a substantially greater number of species than does the extant flora.

The reason for the paucity of speciation in seagrasses remains a subject of intense debate, involving many possible constraints which operate collectively to result in the remarkably low membership of the seagrass flora. The evolution of the land angiosperm flora is closely associated to a coevolution with insect pollinators. The fact that there are no insects in the sea has been used to argue that the very low extent of speciation in the seagrass flora is attributable to the inefficiency of hydrophilous pollination (Van der Hage, 1996). The stress associated with submerged life in a highly saline, high-energy environment may also further constrain the number of species which have been capable of undergoing the needed physiological, anatomical, and architectural (all seagrass species are rhizomatous) adjustments. No single constraint can be invoked in isolation to account for the low number of marine angiosperm species. The constraints imposed by hydrophilous pollination are not likely to differ much from those associated with the fertilization of red algae, the most species-rich phylum of marine algae. The adaptation of angiosperms to underwater life has led to approximately 500 species in fresh waters, and hundreds of angiosperms have adapted to life in saline environments. In addition to these factors, the greater possibilities for exchange of genetic material between distant populations in the sea, which reduces allopatric isolation, may

have played an important role in accounting for the small number of marine angiosperms when compared with the apparent shorter-range exchange between angiosperms on land or in fresh water (Ackerman, 1998).

Seagrass Biogeography and Species Richness

The continuity of the marine environment across large spatial scales is best portrayed by the vast distributional ranges of many seagrass species, as exemplified by *Zostera marina*, which extends from subtropical to subarctic waters. Basically, only nine floras, including some areas of overlap, can be identified (Table 1 and Figure 2) in the shallow, coastal areas inhabited by seagrasses in between polar waters (Hemminga and Duarte, 2000). Six of these species assemblages are composed of temperate species, and only two are represented by exclusively tropical (or subtropical) species.

The biogeographic patterns of seagrass floras are parallel to those followed by hermatypic corals, tropical fish, and mangrove species, all of which reach their highest diversity in the Indo-Pacific region, centered at Malaysia, which is believed to represent the center of origin of these organisms. Indeed, the number of seagrass species declines sharply with increasing distance from the region of highest diversity along the major oceanic currents in the region (Mukai, 1993).

Figure 2 The distribution of seagrass floras. The species present in each flora are listed in [Table 1](#).

The boundaries between seagrass floras are often sharp, corresponding to frontal areas separating different water masses, such as the Almería-Oran density front separating Atlantic from Mediterranean surface waters. Oceanographic fronts act as physical barriers for the dispersal of organisms, preventing the dispersal of seagrass propagules. The importance of major oceanographic fronts as boundaries between different seagrass floras indirectly validates the perception that the low number of seagrass floras and species result from the continuity of the marine environment over large scales.

Geographically isolated floras, however, have many common characteristics, such as the presence of congeneric species assemblages in distant floras such as the twin assemblage of *Thalassia*–*Halodule*–*Syringodium* in the Caribbean and the Indo-Pacific regions and *Zostera*–*Phyllospadix* species in both sides of the temperate Pacific zone ([Figure 2](#)). Single genera are also common to different floras, such as *Posidonia* present in the Mediterranean and Southern Australian floras ([Table 1](#) and [Figure 2](#)). The occurrence of twin species suggests an even wider early distribution of the species, separated by the rearrangements of continental mass and local extinctions. The high species richness in the Indo-Pacific region ([Figure 2](#)) suggests that this may have represented an area of particularly high speciation acting as a focus for radiative dispersal of the species or that, alternatively, extinctions have been fewer there.

Distribution and Controls of Seagrass Species Diversity

Distribution and Controls at the Global Scale

The biogeographic factor constraining the distribution of floras is the major determinant of species richness at the global scale because it sets the maximum species richness possible at any one site. This maximum, however, may never be realized. For

example, in Western Australia, the flora contains many species which often grow segregated, forming mostly monospecific stands. The maximum species richness reported at any one stand is 12 species, but the majority of meadows studied are monospecific, with an exponential decline in the number of meadows with increasing number of species ([Figure 3](#)). The mean richness of 596 descriptions of seagrass meadows encountered in a thorough revision of the published literature is approximately two seagrass species per meadow (mean $\pm$ SE = 1.99 ± 0.07 ; [Hemminga and Duarte, 2000](#)). The resulting diversity, as calculated from the biomass distribution of the seagrasses using the Shannon–Weaver index, is closely linked to the species richness. The majority of seagrass meadows are monospecific and therefore have the minimum diversity index of 0. The highest Shannon–Weaver diversity index for a seagrass meadow was 1.56 for a seagrass meadow containing seven seagrass species in Bolinao (Pangasinan Province, the Philippines), and indices > 1 have only been reported for meadows in the Indo-Pacific region, although the available estimates for such comparisons are few. These values compare poorly with diversity indices calculated for most other marine taxa, which generally oscillate between 1 and 4 for marine algae, invertebrates, and fish assemblages ([Margalef, 1980](#)).

The low species richness of seagrass stands, with most meadows being monospecific or containing two species, extends to areas occupied by floras with high numbers of species, such as Western Australia, in which species tend to be segregated. Mixed meadows, however, are common in the Red Sea and the Indo-Pacific region ([Figure 4](#)), with the highest species richness found in Philippines waters. As a result of these patterns, seagrass species richness shows a clear latitudinal pattern, with the average number of seagrass species being greatest in meadows near the equator and least in meadows in cold, temperate areas ([Figure 5](#)). The seagrass species richness in the subtropics in the Southern Hemisphere is somewhat greater than that for similar latitudes in the

Northern Hemisphere (Figure 5), reflecting the high species richness in the Australian continent and the Indian Ocean. The pattern toward species richness declining from the tropics to the cold temperate zone is comparable to those described for terrestrial taxa.

Figure 3 The number of species present in 596 seagrass meadows reported in the literature.

Distribution and Controls at the Regional Scale

The species richness encountered at any one location is constrained by the size of the flora present in the particular biogeographic region and the suitability of growth conditions in the area to support the different species. The study of the habitat requirements of seagrasses has received considerable attention and is relatively well delineated. Seagrass life is restricted to marine waters, extending to estuarine areas with low salinity, such as those encountered in the Baltic Sea. Seagrasses are further constrained by exposure to desiccation and physical disturbance by waves or, in cold seas, ice scouring in shallow waters, and the downslope limit is imposed by light, with seagrasses penetrating to a depth receiving, on average, 11% of the surface irradiance (Duarte, 1991). Within these limits, seagrasses require appropriate substratum which, for most species—except *Phyllospadix*, *Amphibolis*, and *Posidonia*, which are able to grow attached to rocks—is sandy to silty sediments. Highly silted sediments, which are also associated with reduced sediment conditions and accumulation of phytotoxins, are not appropriate to support seagrass life, which is restricted to sediments with low organic contents, redox potentials above -200 mV, and sulfide concentrations < 100 μ M. Although these growth requirements define habitats appropriate to support seagrass life, different species are expected to have different tolerances to these stress factors, which should lead to differences in species richness among locations at the regional scale.

Species-specific growth requirements are poorly documented for seagrasses, but some regional patterns are

Figure 4 Contour isolines of seagrass species richness generated from data on 596 seagrass meadows reported in the literature.

Figure 5 The mean ($\pm$ SE) species richness in seagrass meadows growing in different latitudinal ranges. Compiled from data on 596 seagrass meadows encountered in a thorough revision of the literature.

emerging. Seagrass species richness declines along gradients of siltation in Southeast Asian coastal waters, with a steep reduction in species richness as the silt content of the sediments exceeds 15%, and only mono-specific (*E. acoroides*) meadows occur at highly silted locations (Figure 6). That these patterns derive from species-specific differences in the resistance to disturbance has been predicted by theory and verified experimentally (Duarte *et al.*, 1997).

The Maintenance of Local Species Diversity

Seagrass species are closely related and therefore often engage in competitive interactions in the resource-poor environments which they inhabit. Competitive interactions, if strong, could lead to species replacement and the dominance of one species following a period of coexistence. Indeed, disturbance experiments have documented how a period of high diversity during intermediate stages of colonization is followed by the dominance by the climax species, which is typically slow growing. That the occurrence of such monospecific stands of climax species may result from strong resource limitation has been demonstrated by long-term fertilization experiments of a monospecific *Thalassia testudinum* meadow, which was colonized by the pioneer species *Halodule wrightii* following experimental nutrient additions (Fourqurean *et al.*, 1995).

High disturbance is also expected to lead to species-poor meadows which contain only small, pioneer species capable of fast colonization and growth, often arrested in a permanent stage of colonization. This is best illustrated by the occurrence of meadows containing only *Halophila* species in areas visited by dugongs in Southeast Asia. The grazing mode of the dugong uproots the seagrass, creating small gaps (feeding tracks about 2 m long and 30 cm wide) that must be recolonized in between successive visits. Only the small *Halophila* species, able to grow

Figure 6 The reduction in the average species richness and community biomass of Southeast Asian seagrass meadows with increasing sediment silt content (Reproduced from Terrados J, Duarte CM, Fortes MD, *et al.* (1997) Changes in community structure and biomass of seagrass communities along gradients of siltation in SE Asia. *Est. Coastal Shelf Sci.* 46: 757–768.).

9 m annually, are sufficiently fast colonizers to withstand this pressure. Because *Halophila* leaves are also tender, low in fibers, and nutrient rich, dugongs have been postulated to be actively farming these seagrass species (Preen, 1995).

Hence, seagrass species diversity is expected to comply with the intermediate disturbance hypothesis, in which the highest diversity is expected at moderate levels of disturbance. Multi-specific seagrass meadows would therefore develop in the presence of moderate disturbance levels. The maintenance of the high species diversity in the most diverse meadow reported to date, located in the Philippines, has been attributed to the disturbance induced by the activity of burrowing shrimps, which maintain small-scale ($< m^{-2}$) patchiness by generating gaps that allow the proliferation of pioneer species in meadows otherwise dominated by large, climax species (Duarte *et al.*, 1997).

Although the preceding discussion highlights the role of competitive interactions, there is also evidence of positive interactions whereby the presence of some species may facilitate the occurrence of other species, thereby maintaining high seagrass diversity. This role has been assigned to “engineering species” (Duarte *et al.*, 1997) able to modify the growth conditions to improve their suitability to maintain plant growth. The occurrence of some seagrass species in Southeast Asia has been reported to be associated with the presence of the dominant species, *Thalassia hemprichii*, which is also linked to high biomass development in the meadows (Terrados *et al.*, 1997). Seagrasses are able to alter the sedimentary conditions in which they grow, injecting oxygen into the sediments through their roots, thereby avoiding the accumulation of phytotoxins produced under anoxic conditions. Through this effect, seagrass species with extensive root systems, such as *T. hemprichii*, may maintain sediment conditions tolerable for seagrass growth where the organic loading derived from the seagrass growth would otherwise render sediments highly reduced and unsuitable for seagrass growth.

Seagrass Genetic Diversity

Seagrasses are clonal organisms, so the genetic diversity present in meadows may be low. Indeed, vegetative reproduction is by far the dominant mode of propagation of seagrasses; therefore, the hypothesis that entire meadows may be composed of one or a few organisms cannot be rejected without serious consideration. Some aspects of seagrass biology, such as the occurrence of mass mortality across large spatial scales, have been ascribed to the dominance of vegetative reproduction in seagrasses and an assumed low genetic diversity to resist diseases. However, examinations of seagrass genetic diversity are still few and have lagged well behind studies of genetic diversity in other angiosperm groups.

The introduction in the mid-1990s of molecular techniques to quantify the extent of genetic diversity of seagrass populations is now providing the needed information to test the assumed low genetic diversity of the meadows. Examination of the genetic structure of seagrass populations has shown considerable variability in the extent of genetic diversity within and among species. Genetic diversity can be important in some of the species investigated (e.g., *Posidonia australis*, *T. testudinum*, *Halodule uninervis*, and *Z. marina*), whereas very low levels of genetic variability have been demonstrated for other species (e.g., *Amphibolis antarctica* and *Posidonia oceanica*). Even in the genetically variable species, most of the variation is found within local populations, and there is reduced gene flow at scales of only a few kilometers or even meters along the depth gradients.

The level of genetic uniformity of seagrasses appears to be greater than that typical of terrestrial plants, supporting the view that the low levels of speciation in seagrasses could derive from inefficient sexual reproduction. The significant within-meadow variability in some species falsifies the assumption that seagrasses are primarily clonal and challenges the explanation of high clonality as the factor responsible for large-scale decline in *Z. marina*, the populations of which show considerable genetic variability. In contrast, the widespread

decline of *P. oceanica* in the Mediterranean could be associated with its high clonality. Although some genetic variation has been reported for populations along depth gradients, sizable variation has only been found near *P. oceanica*'s biogeographical limit in the Mediterranean–Atlantic transition zone. Indeed, a seagrass (*Z. marina*) clone growing in the Baltic has been identified as the largest and oldest marine organism found to date (Reusch *et al.*, 1999). The results to date provide no patterns of possible regulatory factors in seagrass genetic diversity because the differences observed among species do not appear to correspond to differences in reproductive mode or dispersal properties. The study of the genetic structure of the seagrass population is an active area of research; therefore, more robust conclusions than those currently available are expected to be derived in the near future.

Biological Diversity in the Seagrass Habitat

As indicated previously, seagrass ecosystems are important reservoirs of biological diversity in the sea. Seagrass ecosystems tend to contain more species than the adjacent unvegetated bottoms, and the species common to both seagrass meadows and unvegetated areas tend to be more abundant within the meadows. The enhanced biological diversity and richness within seagrass meadows result from their importance as habitat for (i) species that use seagrasses, and the rich detritus they produce, as food sources; (ii) species that use seagrass surfaces as substratum; and (iii) species that seek refuge within seagrass meadows. These species encompass a broad taxonomic spectrum from fungi to mammals.

Microbial Diversity

The abundance of microbial communities appears to be enhanced within seagrass meadows compared to adjacent bare sediments. These microbial communities benefit from the large amounts of detritus seagrass produces as well as the efficient retention of carbon deposited from the water column in vegetated sediments. As a result, there seems to be clear links between bacterial activity and seagrass production and nutritional status, and exploratory analyses have shown that seagrass meadows host highly diverse bacterial communities. The association between seagrass meadows and fungi is even clearer because seagrass rhizomes and roots are heavily colonized by fungi, although mycorrhizal-type associations do not appear to have been developed in the sea. In fact, some of these fungal species may be pathogenic; in particular, the pathogenic *Laberynthula* species have been found to be widespread in seagrass stands. *Laberynthula* species were associated with large-scale seagrass (*Z. marina*) declines in the Atlantic in the 1930s, although the role of these pathogens on the decline remains hypothetical. Recent analyses have also reported a rich ciliate community to be associated with seagrass leaves. This ciliate community encompasses a wide diversity of taxa, and their role in the seagrass ecosystems has yet to be elucidated. These microbial communities may rely directly on detritus produced by seagrasses or benefit from the trapping of particles within the quiescent waters within seagrass canopies.

The best studied microbial community associated with seagrass meadows is the epiphytic microalgal community that develops on the seagrass leaves. This community is largely represented by large benthic diatoms, which colonize newly produced seagrass leaves and are replaced, as the age of the leaf substratum increases, by macroalgae and sessile invertebrate communities. Hence, there is a gradation in epiphytic community structure from the younger leaf base toward the leaf apex, particularly in species with long leaf life spans such as the Mediterranean seagrass *P. oceanica*, the leaves of which last for about a year. The epiphytic community is an important component of the ecosystem metabolism within seagrass meadows, often supporting a primary production comparable to that of the host plants; it also makes an important contribution to heterotrophic processes. In addition, the epiphytic community is responsible for high deposition rates of carbonates on seagrass surfaces, particularly in warm waters, and is therefore responsible for the high carbonate deposition in seagrass sediments.

Macroalgae

Macroalgae often live in association with seagrasses, prominently as epiphytes on the leaf apices of species with long leaf life spans. The number of epiphytic macroalgae species exceeds 350, including all major taxonomic divisions, in which blue-green algae are relatively rare. Competitive interactions and other negative effects are particularly intense in eutrophic environments because the abundance of opportunistic algae (*Ulva*, *Enteromorpha*, and *Chaetomorpha*) is promoted under high nutrient loading. The growth of these opportunistic algae can be so extreme that they can develop thick blankets over the seagrass meadows, which may suffocate or uplift (from the buoyancy due to gaseous release) the plants. In addition, competitive interactions may also be established with the siphonales, notably species of the genus *Caulerpa*, the rhizoids of which confer them the ability to extend horizontally over soft sediments and exploit the sediment nutrient pools. Seagrass meadows in Southeast Asia often contain many *Caulerpa* species. Introduction of *Caulerpa* species (*C. taxifolia* and, recently, *C. racemosa*) to the Mediterranean poses an important threat, where invasive expansion occurs, to the seagrass meadows (e.g., *P. oceanica*).

Invertebrates

The invertebrate fauna associated with seagrasses is very rich, including a multitude of organisms living epiphytically on their leaves and on their rhizomes and associated with seagrasses on the sediments. Epiphytic fauna comprise more than 170 species. Meiofauna include nematodes, rotifers, tardigrades, copepods (planktonic and epibenthic harpacticoid species), and ostracods. Copepods and other free-living zooplankters often swarm within seagrass beds. The leaves support a rich community of epiphytic filter-feeding sessile organisms, including hydrozans, ascideans, and bryozoans. Spongi grow attached to the seagrass rhizomes exposed aboveground and sometimes epiphytically on their leaves (e.g., *E. acoroides*). Polychaetes are abundant within seagrass

sediments and also reach high densities on exposed seagrass rhizomes. Borer polychaetes have been reported to cause damage to seagrass leaves and rhizomes.

Gastropods rank among the most abundant organisms on seagrass leaves, on which they graze the epiphytic algae and sometimes erode the leaf epidermis, damaging the seagrasses. The large gastropod *Strombus gigas*, the queen conch, is an important consumer in Caribbean *T. testudinum* meadows, but heavy fishing pressure has decimated its populations. Seagrass beds are important habitat for bivalves including scallops, which show behavioral adaptations toward a preferential recruitment to seagrass beds. Bivalves may experience an increased growth rate within seagrass beds, as reported for Mercenaria clams and mussels, due to the particle trapping by seagrasses and may also be less prone to predation there. These bivalve populations engage in mutualistic relationships with the plants, such as those reported for blue mussels (*Mytilus edulis*) and temperate seagrasses, because their enhanced activity within seagrass beds provides inorganic nutrients to the surrounding waters and sediments which promote seagrass growth. An outstanding association between seagrasses and bivalves is that by *Pinna nobilis*, a very large (up to 80cm tall) bivalve that is largely restricted to *P. oceanica* beds. *Pinna nobilis* is a protected Mediterranean species and is particularly endangered because, in addition to direct threats from collection and predation, its populations are declining as a result of the widespread decline of *P. oceanica* across the western Mediterranean. Furthermore, *P. nobilis* is the host of a crustacean species (*Pontonia pinnophylax*) which lives in mutualistic association inside its large shell and is also an endangered species because of the decimated populations of the host bivalve. This nested association between *P. oceanica*, *P. nobilis*, and *P. pinnophylax* has been termed a "biodiversity Russian doll" (Richardson *et al.*, 1997) and used as a paradigm of how the threat to landscape components, such as seagrass meadows, involves a threat to the many species therein contained. Although nudibranchs are not particularly prominent components of seagrass beds, sea hares (*Aplysia*) have been observed to graze on seagrass leaves, particularly when gathering in large numbers during the reproductive season.

Isopods and amphipods are major consumers of both seagrasses and their epiphytes. In particular, the isopod *Idotea* plays an important role as a link between seagrasses and higher trophic levels in food webs. Amphipods rank among the most abundant organisms within seagrass meadows. Thalassinid shrimps are important components of seagrass meadows, particularly in tropical waters in which their burrowing activity generates gaps within the seagrass and affects the growth of the adjacent shoots. Thalassinid shrimps can also be major grazers in seagrass meadows, removing up to 30% of their production. Thalassinid shrimps clip leaves of seagrass species adjacent to their burrows and transport them into the burrows to decompose prior to consumption. In addition, their burrowing activity and the active and passive ventilation of their burrows appear to have a major effect on the sediment conditions, attenuating the reduced stage of the sediment while increasing nutrient availability, which may promote seagrass growth. Hence, Thalassinid shrimps are important engineering species within (particularly tropical) seagrass beds, in which their disturbance effect has been

equated to that of typhoons and is responsible for generating small-scale, highly dynamics gaps that are believed to be essential for maintaining multispecific seagrass beds (see Distribution and Controls of Seagrass Species Diversity). Seagrass beds are also important nursery areas for prawns such as tiger prawns (e.g., *Penaeus semisulcatus* and *P. esculentus* in Australian waters), which have been found to feed on seagrass seeds, and caridean shrimps are abundant in subtropical and tropical seagrass meadows. Decapod crustaceans such as *Callinectes* spp. can also be important predators of seagrass seeds. Fiddler crabs (*Uca* spp.) are also very abundant in tropical and subtropical intertidal beds, in which they use their developed claw to remove the epiphytes of the seagrass leaves for consumption.

Detritivore echinoderms, such as holothurids and ophiurids, and herbivores such as sea urchins are abundant within seagrass meadows and are among the dominant invertebrate components therein. Sea urchins can graze heavily on seagrass leaves—to the point that sudden population outbreaks may defoliate seagrass meadows over vast areas.

Vertebrates

The fish communities within seagrass beds typically comprise between 12 and 50 species in any one meadow. Fish communities tend to be more abundant within seagrass meadows than in adjacent bare bottoms, and they seem to seek refuge from predation there or benefit from the higher prey densities often encountered within the seagrass bed. Only approximately 20 species worldwide graze on seagrass. Some species, however, graze on seagrass and/or the epiphytes present on their leaves, such as *Boops salpa* (a herbivorous species in the Mediterranean), parrot fish, and rabbit fish (*Syngnatus* sp.). Cryptic species such as stonefish are often encountered within seagrass meadows, and gobids are also abundant in seagrass meadows, sometimes in association with Thalassinid shrimps. Active predators are often observed visiting seagrass meadows to prey on the abundant animal resources present therein. Other species, such as rays, can act as important disturbance agents by uprooting the plants when hiding under the sediment. Demersal fish production has been found to correlate with seagrass biomass, likely reflecting the higher prey production within these ecosystems.

The main reptile users of seagrass beds are adult sea turtles, which are important consumers of seagrass meadows. The most studied species is the green turtle, *Chelonia mydas*, which grazes on the seagrass. The association of turtles with seagrass meadows is so strong as to be reflected in some vernacular names (e.g., turtlegrass for the Caribbean species *T. testudinum*). Their importance as grazers in seagrass beds, however, has decreased due to the decline of the populations. In Southeast Asia, sea snakes are often observed foraging on seagrass beds.

In temperate climates, intertidal seagrass beds (mostly *Zostera* sp.) often support migrant goose and swan populations. They are the most important vertebrate grazers in cold, temperate waters, in which low water temperature would hamper the digestibility of seagrasses by poikilotherm grazers. Goose and swans feed on both leaves and rhizomes, and they

Figure 7 A *Halophila ovalis* population in a large intertidal flat visited by dugongs in Con Dao Island (South Vietnam).

may play an important role in the dispersal of the plant seeds. Many bird species, including waders, shore birds, gulls, pelicans, and diving birds, feed on seagrass meadows, particularly on intertidal ones.

The syrenidae or marine cows are large marine herbivores that feed exclusively on seagrasses and, in the case of manatees (Caribbean waters), also on freshwater plants growing in rivers. Dugongs (*Dugong dugong*) prefer fast-growing, small seagrasses, especially *Halophila*, which in Southeast Asia develop large stands in intertidal flats (Figure 7), have low lignin and cellulose contents, and regenerate fast. Dugongs feed by absorbing the sediments through their snouts and filtering out the seagrass while dropping the finer sediment particles. Their feeding activity leaves behind distinct feeding trails, usually approximately 20–30 cm wide and 1 or 2 m long, that are bare of seagrasses. In contrast, manatees graze only on the leaves and do not demonstrate a digging behavior. Dugongs and manatees are threatened and protected throughout their ranges. Although the manatee population is still significant, dugong (Southeast Asia to Australia) populations have disappeared from most of their original range, and sizable populations have only been reported from the Great Barrier Reef. Although active hunting of sea cows has been abandoned, their loss to the point of extinction of local populations continues due to mortality induced by fishing gear, dynamite and cyanide fishing, and accidental collisions. As a result, the dugong is now among the most endangered marine mammals at great risk of extinction.

The Function and Management of Seagrass Diversity

Seagrass meadows are one of the ecosystems that provide most valuable services for the biosphere. They produce approximately 0.60 Gt C year⁻¹ and are responsible for one-sixth of the total net CO₂ uptake by oceanic biota (Duarte and Chiscano, 1999). Seagrasses provide habitat for animals, many of which are economically important or endangered, and also play an important role by stabilizing sediments in coastal areas (Hemminga and Duarte, 2000). These functions are closely linked to seagrass diversity because there is evidence indicating that mixed meadows can support considerably

more biomass and be much more productive than less diverse meadows within regions (Terrados *et al.*, 1997). High seagrass diversity may also be linked to a more effective retention of sediments because the more complex canopies of mixed meadows will achieve a greater dissipation of energy by acting at different scales of the energy spectrum than the simpler canopies of monospecific meadows. They are also expected to host a larger number of animal taxa than monospecific ones because of their diversity of substrate and food types. However, the possible functional roles of seagrass diversity remain largely untested, as is unfortunately the case for most other marine taxa.

The importance of seagrass meadows as components of marine diversity does not stem primarily from the diversity of the angiosperm but rather, as indicated previously, from the high diversity that these ecosystems harbor. The role of seagrass meadows as sites of enhanced marine diversity was first addressed in the study of commercially important species, which often use seagrass meadows as nurseries. These studies were later extended to the study of endangered marine organisms, such as marine turtles and dugongs, which rely on seagrasses for food. Indeed, marine biodiversity presents a nested structure within seagrass meadows, which contain endangered species that often act as hosts for species that are necessarily rare, such as the *P. oceanica*—*P. nobilis* (mollusca)—*P. pinnophyla* (decapoda) association described in Mediterranean waters (Richardson *et al.*, 1997). The pattern toward high biological diversity within seagrass meadows has been further strengthened by the demonstration of high microbial diversity, with the leaves of seagrass species containing complex microbial assemblages (fungi, bacteria, microalgae, ciliates, and flagellates) which benefit from the substratum offered by the plants as well as their release of detrital carbon to support these active microbial food webs. The plants also benefit from the activity of epiphyte grazers that prevent an excessive accretion on seagrass leaves, alleviating the negative effects of moderate levels of eutrophication for the seagrasses. Seagrass ecosystems also support food webs distant from the meadows; exported seagrass material has been documented as the carbon basis for some deep-sea communities, and seagrass material accumulating on shore, which may form mounds up to 3 m in height, is used by insects and other terrestrial animals.

Managing Seagrass Diversity: Threats

The limited number of seagrass species in the ocean implies that threats to one or a few species may have devastating consequences for the overall diversity of these plants. Unfortunately, catastrophic seagrass decline has been reported for many seagrass species (Short and Wyllie-Echevarria, 1996), both locally and across entire basins, such as the wasting disease that decimated *Z. marina* in the Atlantic Ocean in the 1930s and the widespread decline of *P. oceanica* in the Mediterranean Sea (Marbá *et al.*, 1996). These losses often result from direct human-induced disturbance, primarily reduced water clarity derived from increased nutrient loading, but they also involve diffuse sources likely associated with changes in climate (Marbá *et al.*, 1996) which may increase the occurrence of diseases (Short and Wyllie-Echevarria, 1996). Human

disturbance leading to seagrass loss includes many factors in addition to eutrophication, such as siltation derived from deforestation (Terrados *et al.*, 1997), mechanical damage from boating, dredging, filling, dynamite fishing and trawling, and altered sediment dynamics after coastal constructions (Short and Wyllie-Echevarria, 1996). Remarkably, seagrasses have considerable resistance to the release of toxic compounds (Short and Wyllie-Echevarria, 1996).

The seagrass area lost cannot be quantified due to lack of a reliable baseline information, but it is certainly large since even large meadows may be lost within a few years (Marbá *et al.*, 1996). Concern about the loss of seagrasses, and the associated loss of ecosystem functions, biological diversity, and resources, has been translated into legislation aimed at protecting seagrasses in many countries (e.g., USA, Spain and France), and particular emphasis has been placed on the importance of preserving seagrass meadows at the International Convention of Biological Diversity (i.e., the Rio Convention). The effectiveness of these measures to promote seagrass recovery, however, is uncertain because, although disturbed seagrass meadows can recover, the current capacity to predict this process is meager. Models of seagrass recovery timescales predict vast differences in recovery time among species, with small, fast-growing species being able to recover within a few years provided that adjacent reproductive populations exist, and the recovery of slow-growing, long-lived species such as *P. oceanica* involving timescales of centuries (Duarte, 1995). Therefore, restoration efforts have been designed to speed up recovery, but these efforts have a high cost and can only be implemented in the countries with the strongest economies.

Hence, the management of seagrass biodiversity must be based on prevention measures aimed at achieving sustainability targets. In particular, management practices should be based on the known habitat requirements of seagrasses to maintain water quality targets (particularly water transparency) and sedimentary fluxes (particularly to prevent erosion and reduce burial rates) compatible with seagrass life. Deterioration of these properties will lead to reduced seagrass diversity, species loss, and the loss of the associated seagrass functions and biological diversity in the meadows they form.

South American Natural Ecosystems, Status of

Philip M Fearnside, National Institute for Research in the Amazon (INPA), Brazil

© 2013 Elsevier Inc. All rights reserved.

Glossary

Bioregion One of six biogeographic divisions of South America consisting of contiguous ecoregions. Bioregions are delimited to better address the biogeographic distinctiveness of ecoregions.

Ecoregion A geographically distinct assemblage of natural communities that share a large majority of their species and ecological dynamics, share similar environmental conditions, and interact ecologically in ways that are critical for their long-term persistence.

Ecosystem A set of interacting living and nonliving components in a defined geographic space. Ecosystems

include both plant and animal communities and the soil, water, and other physical elements of their environment.

Major ecosystem type Groups of ecoregions that share minimum area requirements for conservation, response characteristics to major disturbance, and similar levels of β diversity (i.e., the rate of species turnover with distance).

Major habitat type Groups of ecoregions that have similar general structure, climatic regimes, major ecological processes, β diversity, and flora and fauna with similar guild structures and life histories.

Original Extent of Terrestrial Ecosystems

Ecosystems can be classified in many ways, making the number of categories vary widely depending on the use intended. Here, the system adopted by *Dinerstein et al. (1995)* is used. This divides the continent into 95 terrestrial “ecoregions,” exclusive of mangroves. These are grouped into four “major ecosystem types:” tropical broadleaf forests, conifer/temperate broadleaf forests, grasslands/savannas/shrublands, and xeric formations. Within each of these categories are varying numbers of “major habitat types,” such as tropical moist broadleaf forests. These are further divided into nine “bioregions.” Amazonian tropical moist forests, for example, is a bioregion.

The 95 ecoregions, with their hierarchical groupings, are presented in *Table 1*. Also included are the ratings for conservation status, biological distinctiveness, and biodiversity priority derived by *Dinerstein et al. (1995)*. This study made a systematic survey of the status of natural ecosystems in Latin America and the Caribbean (LAC) and applied a uniform methodology to assigning priorities to these ecosystems for conservation efforts. The work was done for the United States Agency for International Development (USAID) by the WWF–US Biodiversity Support Program (BSP). The document is based on three workshops, plus consultations with relevant organizations and individual experts (the list of contributors contains 178 names).

The classification system is hierarchical, starting with four “major ecosystem types” (e.g., Tropical Broadleaf Forests), which are divided into 10 “major habitat types” (e.g., Tropical Moist Broadleaf Forests). These are crossed with six bioregions (e.g., Amazonia) and divided into 95 ecoregions (e.g., Rondônia/Mato Grosso moist forests). The system allows the priority of some ecoregions to be promoted upward based on uniqueness and regional representation, even if indicators of diversity and vulnerability are not so high.

The effort was unusual in emphasizing protection of areas with high β diversity (a measure of the turnover of species along ecological gradients), as well as the more commonly used α diversity (species diversity within a habitat). In the case of

mangroves, the diversity assessed is ecosystem diversity, including aquatic animal life. This avoids mangroves receiving the unjustly low diversity ratings that tend to result when assessments are restrained to terrestrial organisms, especially trees.

Although the ecoregions identified in *Table 1* refer to “natural” (pre-Columbian) ecosystems, it should be emphasized that these had already been subject to millennia of influence by indigenous peoples prior to the arrival of Europeans. This influence continues today, together with much more rapid alterations from such activities as deforestation and logging done by nonindigenous residents. “South America” is taken to include the three Guianas (different from usage by the Food and Agriculture Organization of the United Nations (FAO)) and to exclude Panama (however, in the case of ecoregions that extend into Panama, the area estimates in *Table 1* include the Panamanian portions). The ecoregions are mapped in *Figure 1*. The ecoregion numbering corresponds to *Table 1* and also to the report by *Dinerstein et al. (1995)*; the numbering presented here is not continuous, since the report also includes ecoregions in Mexico, Central America, and the Caribbean. Extensive bibliographic material on the delimitation of the ecoregions and on the state of knowledge about them can be found in *Dinerstein et al. (1995)*.

Mangroves occur along the coasts of Brazil, the three Guianas, Venezuela, Colombia, Ecuador, and northern Peru. *Dinerstein et al. (1995)* divide them into five complexes: Pacific South America, Continental Caribbean, Amazon–Orinoco–Maranhão, Northeast Brazil, and Southeast Brazil. Each complex is further subdivided into 2–5 units, corresponding to distinct segments of coastline. Mangroves are essential to maintain populations and ecological processes in surrounding marine, freshwater, and terrestrial ecosystems.

Present Extent of Terrestrial Ecosystems

Unfortunately, information is not available on the present extent of each of the 95 ecoregions listed in *Table 1*.

^aIncludes cerrado, caatinga, and chaco.

Information on the extent of tropical forests in approximately 1990 is available from the FAO Tropical Forest Resources Survey (FAO, 1993). These data are tabulated by country in Table 2. More recent FAO reports (e.g., FAO, 2010a) provide national data for forests and for woodlands, but without distinguishing between the various groups of ecosystems (such as tropical forest). Forest types are separated in national reports for some countries, including Brazil (FAO, 2010b). Nontropical areas are covered by a variety of national surveys (Harcourt and Sayer, 1996). National data are important because decisions regarding land-use policies and conservation are taken at the national level – not at the levels of bioregions or ecosystem types. Over half of the South American continent is represented by a single country: Brazil (Figure 2).

An idea of the extent of existing ecosystems can be gained from measurements of land cover in 1988 made using 1 × 1 km resolution data from the AVHRR sensor on the NOAA satellite series (Stone *et al.*, 1994). These are tabulated in Table 3.

It should be emphasized that many ecosystems can be heavily disturbed by logging and other activities without the change being evident on satellite imagery. This is true for Landsat TM imagery (30 × 30 m resolution) used for deforestation estimates in Brazil, and the limitations are much greater for 1 × 1 km AVHRR data.

Brazil is the country with the most extensive satellite information on forest cover and its loss. Unfortunately, information on nonforest vegetation types such as cerrado is much less complete. Considerable confusion arises between the FAO classification and others such as the one adopted here because FAO classifies cerrado, caatinga, and chaco as “forests.” FAO classifies areas with only 10% crown cover as “forests” if the trees are 5 m high or if it has “trees able to reach these thresholds *in situ*” (FAO, 2010a, p. 209).

Brazil’s Legal Amazon region originally had 4 million km² of forests, the rest being cerrado and other types of savannas. Agricultural advance was slow until recent decades because of human diseases (especially yellow fever and malaria), infertile soil, and vast distances to markets. These barriers have progressively crumbled, although a range of limiting factors restricts the extent and the duration over which

**Figure 2** Locations mentioned in the text.

many uses of deforested areas can be maintained (Fearnside, 1997a). Deforestation in the region has been predominantly for cattle pasture, with critical contributions to the motivations for the transformation coming from the role of clearing as a means of establishing land tenure and in allowing land to be held and sold for speculative purposes (Fearnside, 2005, 2008).

The Atlantic forests of Brazil (ecoregions 54 and 55) have been almost completely (>95%) destroyed, mainly for

Table 3 Land cover in South America in 1988

Note: All values in thousands of km² or percent. "TMF" includes tropical moist, semideciduous, and gallery forests, "Grasslands" includes those seasonally flooded, "Closed Forest" includes TMF, montane forests, cool and temperate deciduous forests, and tropical seasonal forests, "Degraded Grasslands" includes agriculture, "Desert, Bare Soil" includes inland salt marsh communities, and "Other" includes wet vegetation and mangroves. More recent land-cover maps for South America are available, but without tabulation by country (Eva *et al.*, 2004; Arino *et al.*, 2008; Tateishia *et al.*, 2008).

agriculture, silviculture, and real estate development. Most of what remains of this extraordinarily rich ecosystem is in protected areas, but unprotected areas continue in rapid retreat. These forests are recognized as major “hot spots” of biodiversity (Heywood and Watson, 1995; Myers *et al.*, 2000; Stotz *et al.*, 1996).

In Andean countries, clearing by small farmers has predominated in driving deforestation, in contrast to the predominant role of medium and large cattle ranchers in Brazil. Migration from densely populated areas in the Andean highlands (*altiplano*) has led to settlement in lowland forests areas, with consequent upsurges in clearing (e.g., Rudel and Horowitz, 1993).

Savanna ecosystems have suffered heavy human pressure. The pampas of Argentina and the Uruguayan savannas of Uruguay and Southern Brazil (ecoregions 120 and 121) have largely been converted to agriculture. The Brazilian cerrado, originally covering 2 million km², is the largest ecoregion in South America, as well as holding the largest number of species of any of the world's savannas. The cerrado was largely intact until the mid-1970s. Clearing, especially for soybeans and planted pasture, reduced the cerrado to 55% of its original area by 2002 according to MODIS imagery (Klink and Machado, 2005). The advance of clearing has proceeded at an accelerating pace, speeded by infrastructure projects and an array of government subsidies.

The temperate and coniferous forests of the Southern Cone have been under severe pressure from logging. These forests are usually logged by clear-cutting in a manner similar to their counterparts in the North American temperate zone. This contrasts with the “selective” logging (highgrading for a few species) that characterizes timber extraction from the diverse forests of the tropical region.

Human Use of Converted Areas

Conversion of natural ecosystems to agroecosystems and secondary forests creates landscapes that maintain biodiversity to varying degrees. “Shifting cultivation” as practiced by indigenous peoples and by traditional nonindigenous residents (*caboclos*) in Amazonian forests maintains a substantial part of the original biodiversity. This contrasts with the effect of the vast expanses of cattle pasture that have replaced this, either directly or following a phase of use in pioneer agriculture by small farmers who have recently arrived from other places.

In densely settled areas along the coast of Brazil and in the southern portions of the country, agricultural use has gone through a series of “cycles,” such as sugarcane and coffee. The productivity of many areas has been damaged by soil erosion and other forms of degradation. Cattle pasture is often the land use replacing these crops. Plantation silviculture has grown steadily since the 1970s and covered more than 74,000 km² by 2010. Soybeans (207,000 km² in 2008) have also made large advances.

In Argentina and Uruguay, cattle ranching and wheat and rice farming are major land uses. Natural vegetation is better represented in areas with little agricultural potential, such as mountain and polar areas and arid and semiarid zones.

Human Use of Remaining Natural Habitats

Areas that remain under natural vegetation cover, rather than being converted to other land uses through clearing, are also subject to human use and alteration. Selective logging in tropical forests, for example, leaves much of the basic structure of the ecosystem intact, but also can lead to significant changes that can set in motion a sequence of events leading to complete destruction of the ecosystem. Logging leaves a substantial amount of dead biomass in the forest, including the crowns and stumps of harvested trees and all of the biomass of the many additional trees that are killed by damage sustained during the logging process. Openings created in the canopy allow sunlight and heat to penetrate to the forest floor, drying out the fuel bed more quickly than in unlogged forests. Climatic variations such as those provoked by the El Niño phenomenon make logged forests especially susceptible to entry of fires. Ample opportunities for fires are provided as fields are burned to prepare land for planting and as cattle pastures are burned to control invading weeds. The fires burn slowly through the understory, charring the bases of trees as they go. Many of these trees then die, leading to a positive-feedback process whereby more dead biomass and canopy openings are provided and subsequent fires begin with greater ease, killing still more trees. This can degrade the entire forest within a few years (Nepstad *et al.*, 2001).

Tropical forests are also used for “extractivism,” or the collection of nontimber forest products (NTFPs) such as rubber and Brazil nuts. This does relatively little damage to the forest, although extractivists do have an impact through hunting and through clearing for subsistence crops. The extractivist population can also play a protective role in defending the forest against encroachment by more aggressive actors such as ranchers and loggers. This is the basis of the extractive reserve system in Brazil (see Anderson, 1990).

Savannas are often grazed by cattle without cutting trees. Cerrado (ecoregion 114), “lavrado,” or Guianan savannas (ecoregion 111), the Pantanal wetlands (ecoregion 133), and the llanos of Venezuela (ecoregion 110) are among the savannas often used in this way. Increasing fire frequency, virtually all a result of human-initiated burning, can lead to shifts in species composition and to a drain of nutrients.

Aquatic ecosystems are traditionally exploited by fisheries. This alters the relative abundance of the species present. Use of watercourses as recipients for sewage and other pollutants also affects aquatic life in many ways.

Threats to Remaining Natural Habitats

Terrestrial Ecosystems

Deforestation

Deforestation is the dominant transformation of forested ecosystems that threatens biodiversity. In Brazil, which holds most of the continent's remaining forests, ranching is the dominant use for land once deforested. In the 1990s, soybeans began to enter forested regions, representing a new force in this process (Fearnside, 2001). Soybeans had already been a

major factor in transformation of the cerrado since the 1970s. The most important effect of soybeans is not loss of forest directly planted to the crop, but the extensive infrastructure of waterways, railways, and highways that are built to transport soybeans and the inputs needed to grow them. The cycle of deforestation that has repeatedly occurred along Amazonian highways can be expected to accompany these new access routes (Fearnside, 2007).

Population growth is a fundamental contributor to deforestation and other forms of natural habitat loss. In recent years, however, the redistribution of population through migration has overshadowed the impact of absolute growth in population size. These include migrations from the semiarid Northeast of Brazil to Amazonia, from Paraná to Rondônia, from the highlands of Bolivia, Peru, and Ecuador to the Amazonian lowlands and, in the case of Ecuador, to the Pacific lowlands as well.

Logging and Charcoal Manufacture

Logging is an increasingly important factor in Amazonia, and the catalytic role of this activity in increasing the flammability of the logged forest gives it potential impact far beyond its direct damage. So far, logging in Brazil has been dominated by domestic demand for sawn wood, plywood, and particleboard, which is almost entirely supplied from tropical forests rather than from silvicultural plantations (which produce wood for pulp and, to a lesser extent, charcoal). However, global markets for tropical timber are presently dependent on supplies from Asian forests that will soon come to an end if current rates of exploitation continue. In the 1990s, Asian logging companies began buying land and/or obtaining concessions in such countries as Brazil, Guyana, and Suriname, and pressure from global timber markets can be expected to increase in the future. Asian loggers are also the principal forces in clear-cutting the Valdivian and *Nothofagus* forests of Chile (ecoregions 88 and 89).

In eastern Amazonia, demand for charcoal for pigiron smelting in the Carajás area is a potential threat to forests. Carajás, with the world's largest deposit of high-grade iron ore, is expected to be mined for 400 years at the present rate of exploitation. Wood from native forests is inherently cheaper as a source of biomass for charcoal production as compared to plantation-grown sources. Charcoal manufacture has an impact on the forest both through direct removal (including officially sanctioned forestry management systems) and by increasing the profitability of logging and deforestation (see Anderson, 1990).

Deforestation impacts are magnified by fragmentation and edge effects (Laurance and Bierregaard, 1997). This division of the remaining natural habitat into many small islands surrounded by cattle pastures or other highly modified land uses, together with forming edges with increased entry of light, wind, and foreign organisms, results in many changes in the remaining natural ecosystems. Most of these changes are forms of degradation, such as greatly increased mortality in the trees that provide the dominant component of forest structure. Vine loads on trees near edges also increase, leading to further increase in mortality and susceptibility to windthrow.

Other Threats

Climate change represents a major long-term threat to many South American ecosystems (Fearnside, 2010). In addition to higher temperatures, continued global warming would cause dramatic increases in the frequency and severity of droughts in Amazonia both due to the El Niño phenomenon that is triggered by warming of surface water in the Pacific Ocean (Cox *et al.*, 2004) and due to even faster increases in the frequency of sea-surface temperature anomalies in the Atlantic Ocean such as the one that caused a disastrous drought in 2005 (Cox *et al.*, 2008).

Removal of fauna through hunting is a virtually universal consequence of proximity of human settlements to natural habitats. The removal of fauna can affect seed dispersal, pollination, and other processes needed for maintaining plant and animal communities. Introduction of exotic species also represents a threat to natural ecosystems. Exotic species are a particularly severe problem in the Valdivian and *Nothofagus* forests of Chile (ecoregions 88 and 89).

Mangrove ecosystems are subject to some unique threats. Shrimp culture in mangrove areas has had severe impacts on the coast of Ecuador. Mangroves in Maranhão have been subject to pressure for charcoal manufacture. In São Paulo state mangroves have often suffered from oil spills and are also losing ground to real estate development. This has also affected restingas (ecoregions 176–178).

Aquatic Ecosystems

Dams

Hydroelectric dams have major impacts on river ecosystems by blocking fish migration, by eliminating rapids and replacing well-oxygenated running water with reservoirs that usually have anoxic water in their lower layers. The composition of fish present changes radically and undergoes a succession of changes as reservoirs age. Anoxic water released through the turbines severely reduces fish and freshwater shrimp productivity in the rivers downstream of the dams.

In Brazil, the 2010 Plan, released in 1987, listed more than 300 dams for eventual construction in Brazil, independent of the expected date of completion. Of these, 65 dams were in the Amazon region. Economic difficulties have caused projected construction dates to be successively postponed, but the ultimate number of dams has not changed. Most contentious is the Babaquara Dam (renamed the "Altamira Dam") on the Xingu River, which would flood greater than 6000 km² of forest, much of it in indigenous areas (Fearnside, 2006).

In Chile, the dams planned in Patagonia, together with their transmission line to Santiago, are expected to have major environmental impacts. In Uruguay, at least five major dams are planned for construction in the next few years. Brazilian-financed dams are moving forward in Peru, Bolivia, and Guyana.

Waterways

Industrial waterways, known as *hidrovias* in Brazil, greatly alter aquatic habitats. No less than seven waterways are under construction or planned for soybean transport on barges: the Paraguay–Paraná (*Hidrovia do Pantanal*), the Madeira River

waterway, the Tocantins-Araguaia waterway, the Teles Pires–Tapajós waterway, the Capim River waterway, the Mamoré–Guaporé waterway, and the Rio Branco and Rio Negro–Orinoco waterways. Waterway construction involves blasting rock obstructions, cutting sharp curves, and dredging sediment from the river beds. The Corumbá–Cáceres stretch of the *Hidrovia do Pantanal*, if built, would lower the water level in the Pantanal wetlands (ecoregion 133), threatening one of the world's most renowned concentrations of wildlife.

Other Threats

Other threats to aquatic habitats include sedimentation from soil erosion and landslides. This is severe, for example, in rivers draining steep areas of former Atlantic forest in the coastal mountains of Brazil. Mining for gold, tin, and diamonds in Amazonia can also inject large amounts of sediment into streams and rivers.

Destruction of varzea forest (ecoregion 33) in Amazonia can affect aquatic life through loss of important fish breeding areas and food sources for fruit- and seed-eating fish. Destruction of varzea lakes and overfishing represent additional threats.

Status of Protected Areas

The choice and design of reserves depend on the financial costs and biodiversity benefits of different strategies. In Brazil, rapid creation of lightly protected “paper parks” has been a means of keeping ahead of the advance of barriers to establishment of new conservation units, but emphasis must eventually shift to better protection of existing reserves (Fearnside, 1999).

Creating reserves that include human occupants has a variety of pros and cons (Kramer *et al.*, 1997). Although the effect of humans is not always benign, much larger areas can be brought under protection regimes if human occupants are included (Fearnside, 2003). Additional considerations apply to buffer zones around protected areas. A “fortress approach,” whereby uninhabited reserves are guarded against encroachment by a hostile population in the surrounding area, is believed to be unworkable as a means of protecting biodiversity, in addition to causing injustices for many of the human populations involved.

Priorities for Conservation

Indigenous peoples have the best record of maintaining forest, but negotiation with these peoples is essential in order to ensure maintenance of the large areas of forest they inhabit (Fearnside and Ferraz, 1995). The benefits of environmental services provided by the forest must accrue to those who maintain these forests. Development of mechanisms to capture the value of these services will be a key factor affecting the long-term prospects of natural ecosystems.

In the case of deforestation in Amazonia, a variety of measures could be taken immediately through government action, including changing land tenure establishment procedures so as not to reward deforestation, revoking remaining

incentives, restricting road building and improvement, strengthening requirements for environmental impact statements for proposed development projects, creating employment alternatives, and, in the case of Brazil, levying and collecting taxes that discourage land speculation. A key need is for a better informed process of making decisions on building roads and other infrastructure such that the full array of impacts is taken into account.

Environmental services represent a major value of natural ecosystems, and mechanisms that convert the value of these services into monetary flows that benefit the people who maintain natural habitats could significantly influence future events in the region (Fearnside, 1997b). Environmental services of tropical forests include maintenance of biodiversity, carbon stocks, and water cycling. The water cycling function, although very important for countries in the region, does not affect other continents as the first two services do. At present, avoiding global warming by keeping carbon out of the atmosphere represents a service for which monetary flows are much more likely to result from international negotiations. Activities under the United Nations Framework Convention on Climate Change (UN-FCCC) are at a much more advanced stage of negotiation than is the case either for the Biodiversity Convention or for the “Non-Binding Statement of Principles” and possible future convention on forests.

In the case of carbon, major decisions regarding credits for tropical forest maintenance are pending in ongoing negotiations. Regardless of what is decided, global warming is a permanent consideration that can be expected to receive increasing weight in decision making. The threats to natural ecosystems in South America are many, and recognition of the multiple environmental services provided by them is a key factor in ensuring that substantial areas of each of these ecosystems continue to exist, thereby maintaining their biodiversity.

Acknowledgments

I thank Eric Dinerstein and the World Bank for permission to publish **Figure 1** and **Table 1**, and Tom Stone and the American Society for Photogrammetry and Remote Sensing for permission to publish **Table 3**. Brazil's National Council of Scientific and Technological Development (CNPq305880/2007-1, 573810/2008-7, 575853/2008-5) and National Institute for Research in the Amazon (INPA) provided financial support. SV Wilson and two anonymous reviewers made helpful comments on the manuscript.

Southern (Austral) Ecosystems

Peter H Weston, University of Adelaide and National Herbarium of New South Wales, Royal Botanic Gardens and Domain Trust, NSW, Australia

Robert S Hill, University of Adelaide, SA, Australia

© 2013 Elsevier Inc. All rights reserved.

Glossary

Continental drift The movement of continents as a result of plate tectonic processes. This was especially important for Southern Hemisphere continents.

Disturbance A set of processes that lead to an ecological point crisis, that is, an event or events that are not part of the normal environment for the organisms that are influenced by it and that can be catastrophic in its impact.

Eucalyptus The dominant tree genus in Australia today.

Gondwana The southern supercontinent, named after an ancient kingdom in India. Gondwana rifted apart over many millions of years, giving rise to the current Southern Hemisphere landmasses.

Nothofagus A genus of Southern Hemisphere trees with a classic “Gondwanic” distribution in southern South America, southeastern Australia, New Zealand, New Caledonia, and New Guinea.

Introduction

A large number of plant taxa are shared by New Zealand, southern South America, and southeastern Australia (including Tasmania) but are found nowhere else. Joseph Hooker was so impressed by this pattern that in 1853 he wrote in his Introductory Essay to the Flora Novae-Zelandiae:

...many of the peculiarities of each of the three great areas of land in the southern latitudes are representative ones, effecting a botanical relationship as strong as that which prevails throughout the lands within the Arctic and Northern hemisphere zones, and which is not to be accounted for by any theory of transport or variation, but which is agreeable to the hypothesis of all being members of a once more extensive flora, which has been broken up by geological and climatic causes.

Thus was born the concept of “Southern (austral) ecosystems.” Hooker knew nothing of the geological basis for the patterns that he observed but he thought that they demanded explanation. We now know that the “once more extensive flora” about which he speculated did exist and that the “geological and climatic causes” that he hypothesized were the consequences of continental drift. “Southern (austral) ecosystems” thus comprise an historical entity rather than an ecological class as one finds in a volume of *Ecosystems of the World*.

The Southern Hemisphere is dominated by oceans, and the development of these oceans is critical in understanding the evolution of terrestrial biodiversity of this part of the world. All major southern landmasses, along with some that are now mostly in the Northern Hemisphere, were once part of the supercontinent Gondwana. The breakup of Gondwana, and the consequent movement of the continents that were once part of it, produced vicariant distribution patterns, as observed by Hooker, but it also had other profound effects on the Gondwanic biotas.

History

In 1859, Joseph Hooker further emphasized the close relationship between the floras of the southern landmasses in his

Introductory Essay to the Flora of Tasmania and persisted in maintaining that this must be the relic of a continuous, ancestral flora. His friends and colleagues soon disagreed. In 1859, Charles Darwin in his *Origin of Species* cited Hooker’s austral floristic pattern but not his geological speculations, explaining the pattern primarily as the result of repeated, independent episodes of long-distance dispersal across the Southern Ocean. In 1880, Alfred Russell Wallace in his *Island Life*, while noting that a number of animal taxa, such as the ratite birds, also showed an austral distributional pattern, chose to explain this as the result of waves of southward dispersal from the Northern Hemisphere, followed by extinction in the north. He agreed with Darwin that the austral floristic relationship must be the result of long-distance dispersal. Neither had any time for geological instability on the scale that Hooker had proposed.

These pioneering biogeographers spawned different, competing research traditions that remain alive and distinguishable today. Hooker inspired an intellectual lineage of phytogeographers to search for repeated distributional patterns and to postulate general explanations for them, invoking dispersal and vicariance of entire floras. This approach was applied in extraordinary breadth by Croizat in his “panbiogeographic” analyses of numerous plant and animal distributions. Croizat’s work produced not only a general distributional pattern (“generalized track”) crossing the Southern Ocean, consistent with Hooker’s analysis, but plenty of other general patterns too, including tracks spanning all ocean basins. After 100 years, the Hookerian tradition was still looking for an explanatory geological theory.

A competing (and for long, dominant) research tradition, inspired by Darwin and Wallace, flourished among zoogeographers, paleontologists, and many phytogeographers. The primary aim of this approach was to construct plausible scenarios describing the centers of origin and dispersal histories for particular taxa, based chiefly on their patterns of occurrence in the fossil record, knowledge of their phylogeny, the ecology of extant species, and knowledge of geological history. An example of this tradition is the work of [Darlington \(1965\)](#).

Corroboration of the theory of continental drift through the discovery of plate tectonics in the 1960s vindicated Hooker's approach by providing the former land connections that he had predicted, in the form of the ancient super-continent Gondwana. The transformation from "austral flora" to "Gondwanan biota" did, however, involve a substantial expansion in scope. Its potential boundaries shifted northward to include the whole of South America and Africa, Madagascar, India, all of Australia plus southern New Guinea, and New Caledonia. Refinements in geological reconstruction progressively added more fragments to Gondwana, such as eastern Sulawesi, the "Outer Melanesian Arc" (Solomons to Vanuatu and Fiji), and, eventually, large parts of eastern Asia.

The immediate effect of this geological revolution on biology was to flip the conventional null hypothesis in historical biogeography from long-distance dispersal to overland dispersal. "Darwinian" biogeographers changed the paleogeographic maps on which they plotted dispersal routes but continued to use the same methods as before. A new question was added to their task list: "To what extent can extant distributions be explained by continental drift?"

Different problems exercised the minds of "Hookerian" biogeographers. While a number of Croizat's tracks were corroborated in surprising detail as vicariant patterns, others, such as his trans-Pacific tracks, remained geologically anomalous. It could be argued that all approaches to historical biogeography had been shown by continental drift to be inadequate in some way or other.

The apparent heuristic success of Croizat's track method and the emergence of new cladistic techniques for reconstructing phylogeny inspired the development of a new approach, cladistic (or vicariance) biogeography, in the 1970s and 1980s (see, Humphries, this volume). This is based on the idea that historical biogeographic relationships can be summarized in the same way as phylogenetic relationships: in the form of tree diagrams. However, cladistic biogeographic trees connect areas of endemism occupied by taxa, rather than the taxa themselves. Methods of analysis have been developed that reconcile "area cladograms" for different taxa to produce "general area cladograms," which summarize episodes of biotic dispersal and fragmentation. The optimistic expectation of this approach is that general patterns will dominate such analyses, producing a small number of general area cladograms. Several cladistic biogeographic analyses of austral biotas have been published, most of which reproduce expanded, cladistically resolved versions of Hooker's austral biota. However, the most ambitious of these (San Martín and Ronquist, 2004) produced a general area cladogram for plants that was more congruent with the predictions of long-distance dispersal than the geological area cladogram. In contrast, the general area cladograms for animal groups, and especially for noninsect animals, were more congruent with geology. Ironically, phytogeographers, who had been the main supporters of the Hookerian tradition over the previous 150 years, had provided San Martín and Ronquist with predominantly Darwinian patterns, while zoogeographers, who had been the most enthusiastic advocates of the Darwinian approach, had provided support for Hooker's hypothesis.

The latest methodological advance that has contributed new evidence on the biogeographic history of southern biotas

is relaxed clock molecular dating. This approach is a development of more simplistic methods based on the assumption of a "molecular clock." If a set of homologous DNA sequences, sampled from a clade of biogeographic interest, has accumulated site mutations at a constant rate, then it can be used to calculate the relative age of speciation events. Relaxed clock molecular dating is more sophisticated in that it does not assume a constant evolutionary rate but instead attempts to model the rate of change of the rate of molecular evolution in different lineages and incorporate these estimates into the process of producing a molecular chronogram – a tree diagram in which branch lengths are proportional to estimated time since divergence. Such a chronogram can be "calibrated" by reference to the minimum age of one or more clades, as indicated by the fossil record, in combination with a maximum age constraint. A number of studies based on molecular dating analyses have tested whether a range of plant and animal taxa are old enough to have acquired their disjunct, austral distributions as a result of continental drift. These have suggested that overland dispersal, vicariance, and long-distance dispersal have all contributed to Gondwanic patterns and consequently, that the explanations of both Hooker and Darwin for these patterns were partly correct.

Patterns

In 1853, Hooker counted 77 plant species and "upwards of 100 genera, subgenera, or other well-marked groups of plants" entirely or nearly confined to New Zealand, Australia, and extratropical South America. His analysis has not been replicated but subsequent authors have added additional taxa without attempting to be comprehensive. For example, Crisci *et al.* (1991) added 10 vascular plants as well as 41 invertebrate taxa, one vertebrate family, and one genus of fungi. Some of these additions were taxa found in New Caledonia, New Guinea, and southern Africa, and hence ignored by Hooker. Some include numerous subclades showing overlapping Gondwanic distributions and therefore are more informative than other taxa. The Diamesine and Podonomine Chironomid midges are classic examples of such groups (Brundin, 1966), as is the plant family Proteaceae, for which 15 higher taxa show separate, overlapping Gondwanic distributions (Sauquet *et al.*, 2009).

Clearly, the pattern of disjunct distributions on which Hooker originally based his concept of an austral flora has not been weakened by further research, but has been substantially strengthened by the addition of more botanical examples as well as a large number of zoological ones. What other patterns are relevant to the reconstruction of Gondwanic biogeographic history? The relationships between distributional patterns and other variables such as means of dispersal, area, and climatic factors have been discussed in great detail by Darwinian biogeographers. General area cladograms that specify the putative splitting sequence of Gondwanic biotas are potentially useful, as are estimates of the age of particular taxa derived from molecular dating. Finally, biogeographers of all persuasions have sought to explain patterns of occurrence of austral taxa in the fossil record.

Distributional Patterns in Relation to Means of Dispersal, Climate, and Area

Darwinian biogeographers emphasized a number of patterns that they thought outweighed Hooker's austral pattern and these were reviewed by Darlington (1965). He pointed to the low number of vertebrate taxa that belong to the austral biota: marsupials, chelyid turtles, leptodactylid and hylid frogs, and galaxiid fishes, and of these, only the galaxiids occur in New Zealand. If these dispersed over land between Australia and South America, then why did no other vertebrate groups follow them? Why did hardly any mammals, reptiles, or amphibians walk to New Zealand? Darlington considered plants and insects, which comprise the great majority of austral taxa, to have more effective means of dispersal than most terrestrial vertebrates.

Darlington also argued that climatic patterns were highly significant in explaining austral distributions. The southern parts of South America, Tasmania, and New Zealand are cold and their western sides very wet because of the strong prevailing westerly winds. The austral biota (as circumscribed by Hooker) is largely restricted to these areas. Moreover, strong westerly winds blow directly over parts of Tasmania, New Zealand, and southern South America. The area of land in the Southern Hemisphere tapers off markedly to the south, greatly restricting the amount of land available to the austral biota. This suggested to Darlington that the "southern end of the world" would be a poor evolutionary center. Biological diversity also tapers off to the south. The extreme southern parts of Australia, New Zealand, and South America all have lower biological diversity per unit area than the less climatically extreme areas further north.

General Area Cladograms

Do Gondwanic landmasses share a common ancestral biota to the exclusion of Laurasian landmasses? What are the cladistic interrelationships between different Gondwanic biotas? These are the kinds of questions that cladistic biogeographers are inclined to ask about the Southern Hemisphere. Among the first studies to focus primarily on these questions was that of Humphries (1981), which was based on cladograms for *Nothofagus* and 24 other taxa. Most of these cladograms were derived from precladistic taxonomic treatments and all relied entirely on morphological evidence. Nevertheless, he discerned two general cladistic patterns and concluded that "the two positions for South America ... are probably due to the fact that it is a huge composite area and shouldn't be treated as a single area of endemism" (Humphries, 1981, p. 205).

More recent attempts to resolve a general area cladogram for Gondwanic landmasses have tended to subdivide South America, and sometimes other continents and islands such as Australia, New Zealand, and New Caledonia, into two or more areas for purposes of analysis. They have also been able to use more rigorously produced cladograms, some of which have incorporated molecular data.

The most comprehensive cladistic biogeographic analysis of Gondwanic landmasses yet published, that of Sanmartín and Ronquist (2004), incorporated 72 area cladograms (53 for animal clades, 18 plant clades and one fungal group). The

most striking feature of this analysis was the different cladistic resolutions found for plant and animal groups. The general area-cladogram for the 18 plant clades can be summarized thus:

((New Guinea, New Caledonia), (SW Pacific, SE Asia)), ((N South America, (Holarctic, (Africa, Madagascar))), (S South America, (New Zealand, Australia)))

This pattern is incongruent with what we know of the geological relationships of these continental fragments: New Caledonia clusters with New Guinea (not New Zealand as predicted by geology), Madagascar clusters with Africa (not India), and Australia clusters with New Zealand (not S South America). In all of these cases, continental landmasses cluster with present day near neighbors rather than landmasses to which they were most recently connected by dry land, suggesting that long-distance dispersal has been the dominant process in the creation of these patterns. Detailed reconstructions of biogeographic events associated with nodes in this tree also found significantly higher proportions of dispersals across the Tasman Sea, the Mozambique Channel and the South Atlantic Ocean than would be expected due to chance.

In contrast, the general area cladogram for the 53 animal clades matches geological predictions in clustering Australia with geographically distant southern South America, to which it was connected by continuous continental crust through Antarctica as recently as 35 million years ago (ma), not to its present day nearest neighbor, New Zealand. The noninsect animal area cladogram is even more congruent with geology and can be summarized thus:

(New Caledonia, ((Madagascar, (SE Asia, India)), (N South America, (Holarctic, Africa))), (New Zealand, (S South America, (Australia, New Guinea))))

This not only resolves relationships between Australia, New Guinea, South America, New Zealand, India and Madagascar as predicted by geology, suggesting that information from the oldest Gondwanan vicariance events has been preserved, but it also fails to cluster New Caledonia with any other landmass, perhaps reflecting the suggestion (e.g., Grandcolas *et al.*, 2008) that New Caledonia was completely inundated from the early Paleocene to the Middle Eocene, and was recolonized entirely by long-distance dispersers from diverse sources. Interestingly, the congruent placement of New Zealand in geological and animal area cladograms is inconsistent with recent suggestions (e.g., Waters and Craw, 2006) that New Zealand was completely inundated during the Oligocene.

Relaxed Clock Molecular Dating

Molecular dating analyses have been used to test hypotheses of Gondwanan vicariance by estimating the ages of disjunct clades: if a clade is estimated to be older than the known geological age of separation of the continental fragments on which it occurs, then vicariance cannot be rejected. A number of such studies have recently been published, the results of which have been mixed. Plant and animal taxa that are "classic members" of the austral biota mostly show patterns resulting from biotic dispersal and vicariance, often combined with

some long-distance dispersal. Examples include the plant families Podocarpaceae (Wagstaff, 2004), Atherospermataceae and Monimiaceae (Renner, 2005), Nothofagaceae (Knapp *et al.*, 2005) Araucariaceae, Proteaceae (Barker *et al.*, 2007) and Winteraceae (Marquinez *et al.*, 2009), and animal clades including marsupials chironomid midges, Onychophora (Allwood *et al.*, 2010), and ratite birds (Phillips *et al.*, 2010). In these examples, disjunctions between South America and Australia are almost all older than 35 ma, consistent with the geological age of severance of the land connection between these continents through Antarctica. No plant clades but some animal taxa (e.g., Onychophora, some chironomids) that show disjunctions involving Africa, have been estimated to be older than the age of separation of these continents from the rest of Gondwana (105 ma). However, the great majority of clades showing Australia–New Zealand and Australia–New Caledonia disjunctions are younger than the oldest (84 ma) oceanic crust separating Australia from the largely submerged continent Zealandia, consistent with long-distance dispersal across the Tasman and Coral Seas. Although some of these clades are also estimated to be younger than the postulated Cenozoic marine inundations of New Caledonia and New Zealand (Goldberg *et al.*, 2007; Grandcolas *et al.*, 2008) a sizeable minority are enigmatic in being old enough to pre-date the supposed Oligocene drowning of New Zealand (Renner, 2005; Knapp *et al.*, 2005; Barker *et al.*, 2007; Allwood *et al.*, 2010).

Many other taxa that show austral distribution patterns, especially subclades in the plant families Asteraceae, Aizoaceae, Apiaceae, Boraginaceae, Caryophyllaceae, Fabaceae, Gnetaceae, Orchidaceae, Poaceae, and Plantaginaceae, have been estimated to be too young to have been involved in any Gondwanan vicariance events and their trans-oceanic disjunctions should be attributed to long-distance dispersal, not vicariance (Crisp *et al.*, 2009, and references therein).

Fossil Record

The patterns of occurrence of taxa in the fossil record provide evidence of the minimum ages of taxa and often indicate that they previously had more extensive distributional ranges than today. In most cases, absence of fossils of a taxon from deposits of a particular age or geographic location cannot reasonably be construed as evidence that the taxon really did not exist at that time or place. Absence of fossil evidence can also be due to incompleteness of the fossil record. However, a few taxa fossilize so readily and abundantly and are so reliably identified as fossils that their absence from the record has to be taken seriously as an indication of either true absence or extreme rarity. The angiosperm genus *Nothofagus* falls into this class.

The fossil record has other limitations, the most restrictive of which is the relatively low proportion of taxonomic characters that are preserved. Vertebrates, for example, are usually only represented by skeletal remains. Their “soft parts” and DNA are rarely preserved. Similarly, many plant taxa are represented only by their fossilized pollen grains. While these sometimes display several distinctive synapomorphies diagnostic of particular clades (see, e.g., Sauquet *et al.*, 2009), most

often they do not. Moreover, pollen grains are such simple structures that the probability of convergent evolution of a distinctive pollen type in the ancestor of an extant clade and in a different, extinct taxon, while not being high, is not negligible. Despite these limitations, the fossil record is a rich source of historical information. Rather than inadequately reviewing the paleontological literature pertaining to all Gondwanic taxa, we concentrate on examples of a couple of key angiosperms.

Probably no taxon has been as strongly associated with the concept of the austral biota as *Nothofagus*. In 1853, Hooker included two subgroups (as *Fagus*) in his list of Antarctic plant groups, Darlington (1965) came close to defining his “southern end of the world” on the basis of its distribution, and van Steenis considered it a key genus for plant geography. *Nothofagus* has an exceptionally detailed fossil record, with both pollen and macrofossils relatively common. At least five distinct types of fossil *Nothofagus* pollen are recorded and they include all the extant subgenera, *Lophozonia*, *Fuscospora*, *Nothofagus*, and *Brassospora*, respectively.

Nothofagus pollen is produced in abundance and fossil pollen is extremely common. If *Nothofagus* pollen is not present in sediments then the genus probably was not present in the immediate vicinity. Therefore, the only limitation to determining the early biogeographic history of the genus is the lack of sediments at critical times and places. To a certain extent, dating the earliest appearances of *Nothofagus* in early Campanian sediments of southern Gondwana (Dettmann *et al.*, 1990) by pollen assemblages alone could involve some circularity, since they are sometimes indicator species for the pollen stratigraphy. However, in both southern Australia and the Antarctic Peninsula, where the earliest *Nothofagus* pollen has been found, the grains are preserved in marine sediments that are independently dated using dinoflagellate and invertebrate fossil assemblages. Earliest records of *Nothofagus* pollen date from the early Campanian, making *Nothofagus* one of the oldest extant angiosperm genera in the fossil record. Records of this pollen are from (in the order they appear) Australia, West Antarctica, New Zealand, and South America (Dettmann *et al.*, 1990). By the early Maastrichtian, the *Nothofagus* clade had diversified into all four modern subgenera, first appearing in West Antarctica, shortly thereafter in South America, and subsequently in Australia some 12–15 million years later (Dettmann *et al.*, 1990). According to the pollen records, the last of the modern subgenera to appear in Australia was either the oldest subgenus, *Lophozonia*, or one of the two youngest, *Brassospora*. New Caledonia and New Guinea are devoid of fossils other than subgenus *Brassospora*, the current earliest record being from the Miocene in New Guinea (Dettmann *et al.*, 1990).

In contrast to *Nothofagus*, the eucalypts (Myrtaceae: *Eucalyptus* alliance) have only been proposed as a Gondwanan clade relatively recently. Like many other plant taxa, the pollen grains of most eucalypts are not particularly distinctive and may be confused with those of other myrtaceous groups such as *Syncarpia* and *Metrosideros* (Hill, 1994). They are pollinated by insects, birds, and mammals and produce fewer, less widely dispersed pollen grains than wind-pollinated *Nothofagus*.

Phylogenetic studies (e.g., Para-O *et al.*, 2006) have resulted in the recognition of seven genera of eucalypts:

Eucalyptus, with more than 500 species, nearly all of which are endemic to Australia (several species occur in New Guinea, one of which extends west and northwest to Sulawesi and Mindanao, several occur in the lesser Sunda Islands as far west as Flores); *Corymbia*, with 113 species, restricted to Australia and New Guinea; *Angophora*, with about 20 species restricted to eastern Australia; *Arillastrum* with one species endemic in New Caledonia; *Eucalyptopsis* with one species endemic in New Guinea; *Allosyncarpia*, with one species restricted to Arnhem Land in northern Australia; *Stockwellia*, with one species surviving as a single population in the Queensland wet tropics. Unfortunately, fossil names for eucalypts have not yet been changed to match this new classification, and so all fossils mentioned here are referred to *Eucalyptus*.

In form the species range from low shrubs to the tallest flowering plants in the world. Eucalypts have been estimated to contribute 75% of Australian vegetation, and at the wetter margins of the continent, they dominate nearly all vegetation except rain forest and allied mesic types. Only in the arid Australian interior are eucalypts generally lacking in dominance.

Given their diversity and current dominance, the eucalypts would be expected to yield a complex and challenging fossil record. That this is not the case has been well documented (Hill, 1994). The oldest reliably dated and described Australian macrofossils associated with *Eucalyptus* include tree stumps, leaves and umbels about 20–22 million years old from several sites in the southeast of Australia (Hill, 1994).

The early pollen record of *Eucalyptus* is enigmatic mostly because of the difficulty in identifying eucalypt pollen. However, probable eucalypt pollen is now recorded from the late Paleocene of the Lake Eyre Basin in inland Australia (Hill, 1994).

An intriguing aspect of the fossil record of *Eucalyptus* is its apparent presence in both South America and New Zealand. A group of three fruits from probable Eocene sediments in Patagonia have been described as *Eucalyptus patagonica*, although there is some doubt as to whether they belong to the *Eucalyptus* alliance (Hill, 1994). However, Gandolfo *et al.* (2011) recently described exquisitely preserved leaves, flower buds, and fruits of *Eucalyptus* *sensu stricto*, with the flower buds assigned to *Eucalyptus* subgenus *Symphyomyrtus*. The full ramifications of these fossils will take some time to appear. Leaves from early Miocene sediments in the South Island of New Zealand are very similar to many *Eucalyptus* species and occur with eucalypt-like fructifications. This record appears to be very good, especially when it is considered in conjunction with the pollen record, since *Eucalyptus* pollen in New Zealand occurs from the Miocene–early Pleistocene, suggesting a relatively recent extinction.

Processes

The complex patterns described here for the Southern Hemisphere biota suggest complex processes, and we still have much to learn about the way in which the Southern Hemisphere biota was molded into its living form. In the following section we briefly mention some of the more likely processes that have been inferred to have had a significant impact.

Continental Drift

Although the precise detail of the breakup of Gondwana is still being refined, our broad understanding is robust and very important for the history of the biota. When continent-sized landmasses rift apart there must be profound direct and/or indirect consequences for the biota. These include changes in climate as the various landmasses move into and out of different climatic zones and the altered relative position of the continents can also influence climate, for example, by altering ocean currents on a massive scale. Plate convergence resulting in subduction, volcanism and continental collision has also profoundly influenced biotas by bringing once separate communities into secondary contact, creating new environments such as mountain ranges and driving extinction.

Vicariance

The most obvious direct consequence of continental rifting is vicariance, the physical separation of once continuous populations of species, which must have often led to allopatric speciation as conditions on the resultant landmasses changed relative to one another.

Biotic Dispersal

Dispersal and intermixing of whole communities and biotas over land has clearly been an important process in the assembly of terrestrial ecosystems throughout evolutionary history. Such processes would have been responsible for the establishment of numerous sympatric distributions of widespread ancestral taxa on Gondwana, as well as the progressively smaller supercontinents that formed and were sundered during the process of Gondwanan fragmentation. This process has also been facilitated by continental collisions and tectonic accretion, most notably the collisions between the northward-drifting Indian, African, South American and Australian continents and Laurasia, or parts of it, during the Cenozoic Era. The resulting north–south biotic dispersal seems to have been predominantly southward in direction. As the Gondwanan landmasses moved close to their present positions, the opportunity for relatively simple, predominantly land-based dispersal opened in three major regions: from Southeast Asia into Australia, from North America to South America, and from Europe to Africa. There are many compelling examples of such southward dispersals and a smaller number of northward ones.

Long-Distance Dispersal

The Southern Hemisphere is dominated by oceans, which provide formidable barriers to dispersal. However, it seems likely that many organisms have successfully crossed these ocean barriers and formed successful populations at the other end. This is likely to have been in the direction of prevailing winds and associated sea-surface currents – predominantly westerly at temperate southern latitudes and easterly in the tropics. While long-distance dispersal is a fact of life, it is very difficult to provide clear evidence for it and so it is largely recorded on a narrative basis. However, the methodological

inadequacy of long-distance dispersal as a general explanation should not be taken to imply its unreality as a process.

Climate Change

The climate history of the Southern Hemisphere is relatively well known and has clearly undergone major change during the rifting of Gondwana. This has been due to a combination of effects, including altered ocean currents, changing atmospheric CO₂ levels and shifting continental positions. The most obvious place where this has had an impact is Antarctica, and this makes a useful case study to demonstrate the potential impact of climate change.

Antarctica has a long history as a continent close to the South Pole. Throughout the rifting of Gondwana, Antarctica has been one of the more stable landmasses, and although its history is complex, it can be considered as a long-standing high-latitude region. The idea that Antarctica was a source of plants and animals for surrounding high-latitude landmasses such as southern South America, southern Australia, and New Zealand is central to Southern Hemisphere biogeography. However, Antarctica today not only is geographically isolated from the other southern landmasses, but is also far too climatically hostile to support the biota concerned.

Antarctica now has only a very sparse covering of plants near the coastline, only two species of which are vascular. Most of the continent is without plant cover, and where terrestrial plants occur, they are usually lichens and mosses. The Antarctic vertebrate fauna is sea-based, using the land only temporarily. In contrast, there is abundant evidence from Antarctica and adjoining landmasses to demonstrate the presence of complex biotas near the South Pole at times in the past. The almost total lack of vascular plants on Antarctica today testifies to major extinctions on this continent. This rates as one of the most complete regional extinction events in the Earth's history, and it is important for us to understand it now more than ever, since it was indisputably a climate-based extinction.

There is now abundant fossil evidence for complex Cretaceous and Cenozoic forests on Antarctica that contain taxa (or their descendants) that often still occur in high southern latitudes in South America, Australia, and New Zealand (Hill and Scriven, 1995). A combination of plate tectonics and other less well defined factors can be used to explain a very different climate at high latitudes in the past, and physiological research on the extant flora has demonstrated that diverse plant life was possible in Antarctica in the past without other physical changes.

During the Cretaceous at high southern latitudes massive speciation occurred, and there is no doubt that lineages were produced that today occupy niches from the equator down to the furthest southern latitudes at which the biota can survive.

The Cenozoic Antarctic vegetation is known from only limited data, but it appears that it continued to show basic similarities to Paleogene floras from Australia and South America. The separation of Australia from Antarctica began in the late Cretaceous, although opportunities for floristic interchange across restricted water gaps probably persisted well into the Cenozoic. Opening of the Drake Passage began in the

mid Oligocene, but details are lacking concerning the extent of dry land, probably as islands, between the Antarctic Peninsula and South America prior to that date.

The question of when the Cenozoic vegetation of Antarctica was eliminated by increasing cold and ice cover has not yet been answered by the fossil record. This is largely because of the confusion introduced into the spore and pollen record by the recycling of plant microfossils once processes of glacial erosion and sedimentation had begun. However, there is reasonable evidence for a cover of temperate forest in the Eocene, perhaps over much of Antarctica. Truswell (1991) noted that sea-surface temperatures about Antarctica were close to 0 °C after the end of the Eocene, allowing the formation of sea ice; temperatures on land were probably lower, and it is unlikely that anything but a highly specialized, restricted flora would have persisted for long in such conditions. However, sparse Oligocene palynofloras containing relatively abundant *Nothofagus* (at least three subgenera) and a low diversity of other vascular plants have been described from Antarctica (Hill and Scriven, 1995). The data indicate a coastal *Nothofagus* forest that was diverse enough to suggest an extension of temperate forest in the region beyond the Eocene.

Milder sea-surface temperatures adjacent to the lower latitude regions of the northern Antarctic Peninsula probably allowed the persistence there of some form of woody vegetation for even longer, and there are good fossil data to suggest vegetation cover into the late Oligocene at least.

The probable middle to late Pliocene Sirius Formation sediments contain leaves, wood, and pollen in an excellent state of preservation, and there can be no doubt that the plants which produced these fossils were growing in situ on the site at the time the fossils were deposited. A tundra vegetation consisting of at least 18 plant species, including seeds, fruits, flowers, leaves and wood, and some in situ plants has been reported, and this includes leaves, wood and pollen of *Nothofagus* (Ashworth and Cantrill, 2004). Therefore the evidence available suggests progressive extinction from an earlier vegetation in which *Nothofagus* was very diverse.

Disturbance

The angiosperms (flowering plants) play a critical role in the current Southern Hemisphere biota, providing a substantial component of the biodiversity and also acting as an important part of the food chain and niche requirements for many other organisms. Angiosperms probably evolved in the early Cretaceous and radiated worldwide. Early angiosperms probably had generalized pollination and dispersal strategies which made them ideal for long-range dispersal by pioneering the fresh sedimentary surfaces of coastal deltas, lagoons, and tidal flats. During the early Cretaceous, these pioneering early angiosperms or angiosperm ancestors dispersed along coastlines out of the rift valley of West Gondwana (between Africa and South America).

Angiosperms were established generally in Gondwana by Barremian–Aptian times (Dettmann, 1989), and those lineages that were widespread in southern Gondwana by the close of the Cretaceous formed the foundation for the living austral floras. Dettmann (1989) has suggested that rift valley

systems at high southern latitudes acted as migrational pathways for early angiosperms, and this may be because of the high disturbance level in these environments and the early successional nature of these angiosperms.

Some prominent angiosperm taxa from the early high southern latitude flora still exist today, and their ecology is well understood. A good example is *Nothofagus*, which has been studied extensively. South American *Nothofagus* does not usually regenerate continuously at low altitudes, especially at lower latitudes, where climatic conditions favor more complex forests and *Nothofagus* seedlings cannot establish. Instead, *Nothofagus* relies on catastrophic disturbance, a relatively common phenomenon in the highly unstable Andes mountain chain and the Southern Alps of New Zealand, to provide a fresh, cleared substrate which is readily colonized by seedlings. This regeneration behavior is probably very similar to that which occurred early in *Nothofagus* history, when it either occupied dense forests on unstable sites and was unable to regenerate in the absence of disturbance, or was in more sparse forest on less equable sites where its seedlings could survive in the understory. Hill (1994) hypothesized that the large reduction in *Nothofagus* diversity at high latitudes today, especially away from the Andes, may be due to the relative modern stability of the landscape, which, coupled with the density of the forest cover, does not provide the right environment for the continued presence of many *Nothofagus* species.

Thus, at high southern latitudes during the Cretaceous–Paleogene, unstable habitats provided both a pathway for the migration of early angiosperms and also the potential for peripheral isolation of populations of widespread species, which may have been a critical factor for evolution in the region (Hill and Scriven, 1995).

A more recent form of disturbance has been the widespread impact of fire. In Australia, fire history as a major impact on the biota can be traced back to the early Cenozoic at least, but its influence has been particularly profound only in the past 100,000 years or so. Fire is now very significant in areas of the Southern Hemisphere with hot, dry summers.

Plant Growth at High Southern Latitudes

Woody plants no longer grow at very high southern latitudes (e.g., Antarctica), and yet they were a key component of Cretaceous biotas very close to the South Pole. In the past, debate has centered on whether this was possible, since the photoperiods at such high latitudes require long, dark winter periods. The issue is more one of suitable temperatures than suitable photoperiods, but nevertheless, the question remains: How did plants grow and what form did the communities take in such an unusual photoperiod? It is a real limitation of the fossil record in general that behavioral traits such as dormancy rarely leave a clear imprint (Truswell, 1991). Nevertheless, information on physiological adaptations to life at high latitudes can be obtained, especially from fossil wood. Cretaceous gymnospermous wood from paleolatitudes probably higher than 70° S shows a consistent growth pattern, with increments, probably annual in origin, clearly delineated, and indicating a pronounced seasonal influence (Hill and Scriven, 1995).

The amount of wood added annually was usually large, even when compared with modern low-latitude trees, but there is considerable variation in ring widths from year to year, suggesting that the trees were highly sensitive to environmental fluctuations (Truswell, 1991). A fossil forest at one early Cretaceous site had trees spaced 3–5 m apart and the tallest preserved trunk height is 7 m. Hill (1994) used these data to explain the reduction in wind pollination in understory plants during the very early Paleogene in southern Australia. With the sun at a low angle in the sky during summer and tracking an almost circular path around the horizon during the day, he concluded that it was likely that the forest structure was quite different to that observed in heavily forested regions at lower latitudes today. Relatively widely spaced, conical trees probably dominated and this may have continued until at least the late Cretaceous, and thus wind pollination was a viable strategy for understory plants below the open canopy. As today's forest-bearing landmasses moved to lower latitudes and the sun angle increased, a closed forest structure became possible, due to the increase in incoming solar radiation. This may have been critical for the loss of wind pollination as a viable strategy in the associated understory plants.

The presence of a relatively dense plant cover, including large and rapidly growing trees, in regions south of the Antarctic circle, was for a long time viewed as difficult to explain, given that today growth at high latitudes is considered to be constrained by characteristic day-length patterns and by the temperatures associated with a regime of long rigorous winters and short cool summers (Truswell, 1991). However, it is now generally accepted that the light energy at high latitudes was sufficient, at present values of axial obliquity, to maintain forest growth in the past provided the temperatures, particularly in winter, were higher.

Enhanced atmospheric CO₂ levels may have been influential in producing the high annual increments of growth observed in Cretaceous trees. The overall effect of the high predicted levels of CO₂ in the Cretaceous on plant growth are difficult to quantify, since experiments carried out on living plants examine the instantaneous effects of large changes in CO₂ concentration on plants which have evolved to a particular ambient level. When plants have evolved to accommodate higher levels (as in the Cretaceous) the result may have been even more spectacular (Hill and Scriven, 1995).

Conclusion

The biota of the Southern Hemisphere is extremely diverse and is the result of a complex history. However, clear biotic linkages occur among the major landmasses. These linkages have historical significance, with vicariance and long-distance dispersal contributing to the geographic spread of organisms and climate change and disturbance being among the major processes that have led to the living species that occur there. Our knowledge of the history of the Southern Hemisphere is incomplete, but we have enough information from inter-relationships among living organisms and the fossil record to be able to reconstruct at least part of this history with reasonable accuracy. The most important event in the history of

the Southern Hemisphere as it influences the living biota was the rifting of Gondwana. Not only did this separate the biota on to smaller landmasses that subsequently had very different histories, but it also influenced other processes such as climate change and disturbance regime. This distinguishes the Southern Hemisphere biota very clearly from that of the Northern Hemisphere, and it is important not to presume that the processes in the two hemispheres were at all similar.

Glossary

Anchialine (or anchihaline) Haline water, usually with restricted exposure to open air, and always with subterranean connections to the sea.

Epikarst Interface zone between soil and rock characterized by fractures and small solution pockets; an ecotone between surface and subterranean water in karst.

Hypotelminorheic A persistent wet spot, a kind of perched aquifer, rich in organic matter, underlain by a clay layer typically 5–50 cm beneath the surface, with a drainage area typically of less than 10,000 m².

Interstitial The spaces between sediment particles, especially in alluvial deposits.

Milieu souterrain superficiel (MSS) The interstitial spaces deep in the soil and mantle/bedrock interface, as found in glacially fragmented zones. By origin, the milieu

souterrain superficiel, or mesovoid shallow stratum, thus the acronym MSS.

Stygobiont Aquatic species that are obligate subterranean dwellers.

Stygophile Aquatic species that can live and reproduce in both subterranean and surface environments.

Troglobiont Terrestrial species that are obligate subterranean dwellers; sometimes used for aquatic species as well.

Troglophilic Pertaining to the morphological, behavioral, and physiological characters that are convergent in subterranean species.

Troglophile Terrestrial species that can live and reproduce in both subterranean and surface environments; sometimes used for aquatic species as well.

The Subterranean Domain

The subterranean domain, literally the domain below the Earth, includes both air- and water-filled underground habitats. The most celebrated of these are caves. However, the subterranean domain is much more extensive and complex than caves. Subterranean cavities occur in a wide variety of situations. Among them are large spaces such as caves and small spaces such as the interstitial openings between sand grains (Botosaneanu, 1986). Many large spaces, especially karst caves, formed by the action of acidic waters, are in carbonates (particularly limestone) and evaporites (particularly gypsum).

Landscapes in which the primary agent molding the landscape is dissolution rather than erosion are called karst landscapes. Comprising ~15% of the Earth's surface, karst represents 75% of the land area of Cuba, 45% of Slovenia, 25% of France and Italy, and 40% of the US east of Tulsa, Oklahoma. Caves are present in Cambrian rocks, more than 500 million years ago, to Holocene limestone, less than 10,000 years old. Although caves have a reputation as both exotic and rare habitats, they are actually quite common. More than 100,000 caves are known from Europe, and nearly 50,000 are known from the US. Caves come in many sizes and varieties, ranging from a few meters long to Mammoth Cave in Kentucky with a surveyed length of more than 500 km.

All subterranean habitats, whether they have large or small spaces, share several key features (Culver and Pipan, 2009). First, there is a permanent absence of light. Second, productivity is extremely limited, and except for rare cases, primary productivity is absent. Third, almost all systems of water- or air-filled cavities have biological activity. Fourth, there is reduced environmental variability relative to surface conditions. Thus, subterranean organisms must contend with complete

darkness, limited food, and at least a reduction in seasonal cues. Because they are quite different, it is convenient to consider aquatic and terrestrial habitats separately.

Aquatic Subterranean Habitats

Caves are an important part of aquatic ecosystems in karst terrains, but are not the only components (Figure 1). Water enters the subterranean karst system at the rock–soil interface, which typically has many small solution pockets and cavities with complex horizontal and vertical pathways. Eventually, water percolating through the epikarst reaches a cave stream, which in turn exits at a spring and flows into a surface river. Beneath the cave stream is a permanent saturated (phreatic) zone that itself often contains large cavities.

Epikarst is a perched aquifer, and a major ecotone between surface water and cave water. Water is transmitted vertically either through conduits or small fissures to the phreatic zone. Lateral transmission occurs through poorly integrated lateral openings. Its principal characteristic is its heterogeneity, with many semi-isolated solution pockets whose water chemistry is also quite variable. It forms more or less a permanently saturated zone, close under the surface.

The water in cave streams comes from infiltration from the epikarst and from sinking streams. Cave streams formed largely from percolating epikarst water tend to be very stable temporally, whereas cave streams formed largely from sinking surface streams show greater temporal variability. Flow rates of cave streams range from a few milliliters per minute to tens of cubic meters per minute.

A rather unusual habitat, intermediate between an aquatic and terrestrial habitat, is the cave hygroscopic. It is where there is a thin layer of water moving over vertical surfaces, resulting from water percolating from above. The flow of the water is

Figure 1 Idealized cross section of a karst area.

usually laminar rather than turbulent, and it is well oxygenated and often relatively rich in organic matter.

Phreatic water (permanent groundwater) in karst areas is in most ways similar to phreatic water in nonkarst areas except that karst phreatic water has high secondary porosity. Phreatic water has very slow flow rates and consequently long residence times – decades or even centuries. Wells and artesian springs in karst areas often connect with water-filled underground voids, tens to hundreds of meters deep.

As described below, epikarst, cave streams, and the phreatic zone contain distinct communities. Other important aquatic habitats in karst landscapes include intermittent lakes (a much understudied habitat), anchialine water (haline water, usually with restricted exposure to open air, and always with subterranean connections to the sea), hydrothermal waters (both in caves and in springs), and springs (a flow of water rising or issuing naturally out of the earth). It is worth noting that springs come in a wide variety of sizes and shapes, and in countries with extensive karst development such as Slovenia and Croatia, there are multiple words that subdivide the English word “spring.” A specialized aquatic karst habitat has been found in extensive areas of western Australia. These are thin carbonate deposits in isolated, though sometimes extensive pockets formed by evaporation of near-surface waters in very arid climates. They probably have some functional analogies with epikarst, both being relatively shallow subterranean habitats with capacity for water storage, and relatively rich in organic matter.

The aquatic interstitial habitat is comprised of the water-filled spaces between grains of unconsolidated and saturated sediments. These habitats occur in littoral sea bottoms and beaches, freshwater lake benthos, alluvial plains, riverbeds, and

the hyporheic zone (the porous aquifer beneath and lateral to streams). The hyporheic zone of rivers can also be viewed as an ecotone between surface and groundwater. Stability of environmental variables in interstitial habitats generally increases with depth in these habitats. Grain size determines interstitial space as well as many chemical parameters such as oxygen concentration. At a microscale, interstices are interconnected, and the porous medium is heterogeneous and constitutes a mosaic of microenvironments. Interstitial habitats also occur at depths greater than 1 km, and most water wells have microbial community, both Eubacteria and Archaea. In some cases, the microbes probably colonized the habitat as it was being formed. The interstitial habitat is a very ancient one, especially along the margin of seas.

A final aquatic subterranean habitat fits uneasily into any classification scheme. This habitat type is perched aquifers, typically of less than 10,000 m² catchment area, underlain by an impermeable layer, usually clay. Operationally, it is a permanent wet spot in the woods isolated from other surface and groundwater, usually with a black color derived from decaying leaves. This habitat was given the name hypotelminorheic by Mestrov, and the exit of the water to the surface is a seepage spring, according to the classification of Kresic. Also little studied; it may be quite extensive, particularly in regions where there are clay strata.

Terrestrial Subterranean Habitats

The range of terrestrial subterranean habitats is much more restricted than that of aquatic subterranean habitats. Terrestrial

subterranean habitats must of course be above the water table, and in general are less well developed in nonkarst areas. The epikarst habitat has largely been studied by hydrogeologists, but in fact this zone also contains many air-filled cavities, and terrestrial species are routinely collected from epikarst. Both solution caves and lava tubes are important terrestrial habitats. Lava tubes form by the surface-cooling and solidification of lava flows. Under some circumstances, abandoned mines can be an important habitat for hibernating and maternity colonies of bats.

Terrestrial subsurface habitats also occur outside of caves. These include cracks and small voids in volcanic rocks and a superficial zone of rock fissures and debris slopes in a variety of rocks, including limestone, schists, gneiss, etc. Generally occurring at a depth of few meters, this habitat was called *milieu souterrain superficiel* (MSS) in French, or mesovoid shallow substratum in English. The MSS is generally found in mountains in temperate zones but apparently not in the tropics, where voids are usually filled with laterites and clay.

Deep-soil (edaphic) habitats have not traditionally been part of subterranean biology. Deep-soil habitats share all the characteristics of other subterranean habitats except for one – deep-soil habitats tend to be rich in organic matter. However, this distinction is relatively arbitrary and there are other relatively energy-rich subterranean habitats such as the hypotelminorheic and cave guano communities (see Some Representative Cave Communities).

Sources of Energy in Subterranean Environments

All subsurface environments share an absence of light and hence an absence of photosynthesis. With the exception of a few caves and possibly most deep-groundwater habitats with significant chemoautotrophy, there is no significant primary production, that is, no photoautotrophy. With these exceptions, all subsurface food webs rely on the import of surface organic matter in one form or another. For the most part, subterranean habitats are energy poor. The famous Romanian speleobiologist Emil Racovitza stated that many subterranean organisms are “carnivores by predilection but saprophages by necessity” (translation by the authors).

For most aquatic subsurface habitats, organic matter is brought in by the action of water. Dissolved organic matter (DOM) and fine particulate organic matter (FPOM) are important energy sources in interstitial and hypotelminorheic habitats. The source of the organic matter is surface production, and as organic matter is utilized by subterranean organisms, both its quality and quantity decline. DOM and FPOM are also important in subterranean karst habitats. Vertically percolating water from the epikarst (and ultimately surface water) collects in pools and streams, and is often relatively rich in organic matter. In addition, considerable numbers of both terrestrial and aquatic organisms wash out of the epikarst into pools and streams as well. Although some of this “rain” of animals, especially copepods, are able to colonize the pools and streams, others, such as Collembola, survive short periods at most, and are food resources for the cave inhabitants. In many caves, sinking streams (swallets) bring in additional organic matter – not only DOM and

FPOM but also coarse particulate organic matter (CPOM), including leaves and twigs. In a sense, many cave streams are not different from a low-productivity stream on the surface, where allochthonous input greatly exceeds autochthonous production.

For many subsurface terrestrial communities, a major source of energy is the organic matter that is stranded along stream banks as a result of the processes outlined in the previous paragraph. In addition, another source of energy in many caves is the result of the movement of animals in and out of the cave. In many North American caves, cave crickets of the subfamily Rhaphidophorinae periodically leave caves to forage and deposit their eggs in sandy substrates in the cave. These eggs are, in turn, the major part of the diet of some troglobiotic carabid beetles. The fecal material of the cave crickets and the occasional dead cave cricket bodies are an important food supply for other troglobionts. Fecal matter left by other cave visitors is also important in many caves. The most important source of fecal material is bats. In most temperate zone caves, only a few bats use the cave, and their guano is the basis for a group of species whose food base is transitory organic matter. In those temperate zone caves that serve as maternity sites or hibernacula, and in many tropical caves, large bat colonies produce enough guano for there to be a community specialized on the guano. Most of these species are guano specialists rather than cave specialists.

There are other allochthonous sources of food. In a few caves, such as the lava tubes on the Canary Islands and some MSS habitats, the major source of organic matter is wind-carried particles and debris, which penetrate into the subterranean habitats through cracks and fissures. In lava tubes and some shallow limestone caves, roots penetrating through the ceiling are an important food supply, and in some Hawaiian lava tubes there are species that specialize in this resource. Roots are also an important food source in the aquatic calcrete habitats of arid Western Australia.

The possibility of a subterranean chemoautotrophic ecosystem has long intrigued biologists. Movile Cave, a small cave near the Black Sea in Romania, is such an ecosystem. This cave, discovered during geochemical prospecting in 1986, has no natural entrance. Its H_2S -, CH_4 -, and NH_4^{4+} -enriched waters are slightly thermal. A series of air bells occur throughout the cave in which atmospheric composition is enriched in CO_2 and CH_4 and depleted in O_2 . The water surface is covered with a floating mat of bacteria and fungi. Chemoautotrophic production was demonstrated by incorporation of bicarbonate ion by the mat and by the presence of ribulose-1,5-bisphosphate carboxylase-oxygenase, an enzyme characteristic of autotrophic organisms. A Gram-negative rod-shaped bacterium was isolated from the mat that was an obligate autotroph, using the energy of the oxidation of thiosulfate and sulfide. Furthermore, this autotrophic production is the basis not only for the aquatic food web but also for the terrestrial food web – the only documented case of a chemoautotrophic terrestrial ecosystem. Several other sulfide-rich caves, including Frassasi Caves in Italy, Villa Luz Cave in Mexico, and Cesspool Cave in Virginia, also exhibit many features of chemoautotrophic production.

Many phreatic deep systems are chemoautotrophic (actually chemolithoautotrophic). The presence of bacteria in the

deep subsurface was first suggested by Edwin S Bastin in the 1920s. He suggested that the curious presence of hydrogen sulfide and bicarbonate in water extracted from oil was the result of the activity of sulfate-reducing bacteria at depth. It was nearly 60 years before the technology was developed to sample bacteria at depth. To do so the solution of several formidable technical problems was required. The first was to obtain samples uncontaminated by surface microbes, and the second was to characterize the microbes. Characterization of the samples is difficult because of the unusual environmental conditions in which the microbes live, making standard culturing techniques of limited value. Much of our knowledge of deep-groundwater microbes is derived from sampling wells near former nuclear weapons production sites in Washington State and in South Carolina. Bacteria and Archaea have been found at depths of more than 2 km. Their presence in sedimentary rock may be the result of the slow infiltration of water from the surface or they may have been present at the time of the deposition of the rock. The possibility that they were present at the time of deposition is plausible, given the depth of the water and its age based on stable isotope ratios. Microbes present in igneous rock must have been deposited after it formed since it was too hot at the time of formation. In these habitats, chemolithotrophs, which are forms that use inorganic carbon as a carbon source and obtain energy from the oxidation of reduced inorganic chemicals, predominate. The possible great age of some of these microorganisms combined with their ability to survive in the absence of organic matter and sunlight makes it probable that they are more representative of some of the earliest forms of life on the planet than are surface-dwelling microorganisms. They may also be useful analogs for understanding what life on other planets, such as Mars, might be like. More than 9000 strains of organisms have been cataloged from subsurface habitats.

A variety of chemical reactions are used by Eubacteria and Archaea to provide the energy for biosynthesis. Among the reactions occurring in deep-groundwater is methanogenesis:

The methanogenic reaction uses hydrogen gas as the energy source and inorganic CO_2 as the carbon source. Hydrogen derives from the reaction of the oxygen-poor water with iron-bearing minerals. Methanogens can persist indefinitely without any supply of carbon from the surface.

Taxonomic Survey of Subterranean Life

Many organisms spend some or all of their life cycle in caves, particularly cave entrances. The moist rock of cave entrances provides habitat for many mosses and ferns, such as the Hart's tongue fern (*Phyllitis scolopendrium*). The entrance and twilight zone of a cave are refuges from temperature extremes of the surface. Some species, such as the spider *Meta menardi*, are specialized for the surface-subsurface ecotone at cave entrances. The entrance and twilight zones of caves are relatively predator-free, at least for vertebrates. The neotropical oil bird *Steatornis caripensis* nests in caves; many other birds do so as well, albeit on a less regular basis. Many cave entrances in the eastern US

have one or more phoebe (*Sayornis phoebe*) nests. The best-known visitors to caves are bats. Depending on the species, bats use caves as maternity colonies, as hibernacula, and as temporary roosts during the warmer months of the year. More than half of the species of bats found in the eastern US use caves throughout or for part of the year. About 95% of the more than one million gray bats, *Myotis grisescens*, hibernate in eight caves. Many bat species are at risk because of the vulnerability of their hibernating and maternity sites to disturbance. The recently discovered disease, White Nose Syndrome, is rapidly decimating North American cave-inhabiting bats.

Many species spend their entire life cycle in caves. In the case of terrestrial species, troglobionts have an obligate dependence on caves and must complete their entire life cycle in caves. Troglophiles can complete their life cycle in caves, but they can also complete their life cycle in surface habitats. The equivalent terms for aquatic species are stygobionts and stygophiles. Another useful term is troglomorphic, which denotes the morphological syndrome associated with life in caves – loss of eyes and pigment and the elaboration of extra-optic sensory structures. Most but not all troglobionts are troglomorphic. Those that are not, likely have not been isolated in caves for a long enough time for troglomorphic characteristics to evolve, or live in relatively food-rich subterranean habitats.

The remarkable cave amphibian, *Proteus anguinus anguinus*, was the first stygobiont to be mentioned in scientific writing. Writing in 1689, Valvasor reported that local residents thought that this amphibian, common in caves in Slovenia, was the larvae of dragons. Its scientific description was accomplished by Laurenti in 1768. The first troglobiont, the cave beetle *Leptodirus hochenwartii* (Figure 2), was described by Schmidt from the same region in 1832. Currently, more than 4000 troglobionts and 2000 stygobionts have been formally named, and at least several times that number probably exist.

In all subterranean environments, a wide variety of heterotrophic bacteria and Protozoa occur, even in deep-groundwater sites. Early interest in autotrophs in caves centered on the potential role of nitrifiers such as *Nitrobacter* in

Figure 2 The first described troglobiont, the beetle *Leptodirus hochenwartii* from a cave in Slovenia. The length of the beetle is 8 mm. Reproduced with permission from Matija Gogala, Ljubljana, Slovenia.

the formation of saltpeter (KNO_3). There is a wide diversity of metabolic pathways among autotrophs, most important in the carbon-fixing pathways: the Calvin cycle in bacteria, the acetyl-coenzyme A pathway in Archaea, and the reductive citric acid cycle found in Archaea and a few bacteria. There is also considerable diversity in the electron donor and acceptor among subsurface autotrophs. Electron donors include H_2 , NH_4^{4+} , S, and Fe^{2+} ; acceptors include O_2 , SO_4^{2-} , and NO_3^- .

Except for a few protozoans, the Eukarya is usually not found in deep-groundwater. A wide taxonomic array of organisms is stygobiotic or troglomorphic, including the following phyla: Porifera, Hydrozoa, Platyhelminthes, Nematoda, Mollusca, Rotifera, Annelida, Onychophora, Arthropoda, and Chordata.

Among stygobionts, the Crustacea predominate: At least half of the described species are Crustacea. Among the Crustacea, the orders Remipedia, Spelaeogriphacea, and Thermosbaenacea are exclusively stygobiotic. Numerically, crustacean stygobionts are dominated by Copepoda (especially in the interstitial and the epikarst) and Amphipoda (especially in caves). Some Amphipoda genera are particularly speciose. For example, nearly 175 stygobiotic species of the amphipod genus *Stygobromus* are known from North America, and more than 200 stygobiotic species of the amphipod genus *Niphargus* in Europe. Other important groups include the planarians (Platyhelminthes: Tricladida), snails (Mollusca: Gastropoda), salamanders (Chordata: Caudata), and fish (Chordata: Pisces). The surface-dwelling ancestors of these species were largely benthic, and many species were adapted to environments with dim light and a detrital food base.

Among troglomorphic, the Arachnida, Diplopoda, and Insecta predominate. At least 90% of the species are in these groups. Among the Arachnida, spiders (Araneae), false scorpions (Pseudoscorpionida), and harvestmen (Opiliones) are common in temperate caves and in the tropics. Other groups, such as Schizomida, Ricinulei, and Amblypygi, are also important. Among the Insecta, springtails (Collembola) and bristletails (Diplura) are common, but the beetles (Coleoptera) predominate. More than 2000 troglomorphic beetles are known. One genus in the US (*Pseudanophthalmus*) accounts for nearly 250 species, and the European genus *Duvalius* has approximately the same number. Among the cholevid beetles, 23 troglomorphic genera are known from the Pyrenees alone. The surface-dwelling ancestors of many of these species occurred in leaf litter in forests and are believed to have colonized caves during climatic vicissitudes of the Pleistocene.

Although bats are not troglomorphic since they spend part of their life cycle outside of caves foraging for food, their dependence on caves is every bit as profound. Among the nearly 1100 described species of bats, at least one-third utilize caves as day roosts, hibernacula, or maternity sites. For many species, especially those in the Vespertilionidae and Molossidae, there is an obligate dependence on caves. Some species form giant hibernating colonies: more than 90% of *M. grisescens* found east of the Mississippi hibernate in three caves in which numbers may reach more than 1 million. The Mexican free-tailed bat, *Tadarida brasiliensis*, forms large summer maternity colonies, with up to 20 million individuals in a single cave. This species declined in numbers due to the widespread use of dichlorodiphenyltrichloroethane (DDT).

Adaptations to Subterranean Life

Compared with related surface-dwelling species, subterranean animals are characterized by the absence or reduction of a series of features, particularly eyes and pigment. Subterranean animals are also characterized by an elaboration of extra-optic sensory structures as well as other morphological, ecological, physiological, and behavioral adaptations (Table 1). This represents a remarkable convergence among subterranean animals, the morphological aspects of which are called troglomorphy. Of course, not all features are convergent. For example, interstitial species tend to be smaller than surface-dwelling sister taxa while cave species tend to be larger.

What makes subterranean animals particularly interesting in this regard are the obvious and unusual reductions, often called regressive evolution or "evolution in reverse." Unlike some aspects of evolution, such as the evolution of sex and the origin of evolutionary novelty, eyelessness and regressive evolution in general have always appeared easy to explain. To an orthogeneticist such as Albert Vandel writing in the mid-twentieth century, eye loss in subterranean animals was a by-product of a senescent phyletic line. Animals were not blind because they were in caves; rather, they were in caves because they were blind. To a neo-Lamarckian such as Packard writing in the late nineteenth century, eye loss was a classic example of the role of disuse. To a neo-Darwinian, eye loss in subterranean animals was the result of an evolutionary tradeoff resulting from natural selection for elaborated extra-optic sensory structures. To neutral mutationists, eye loss in cave animals was easily explained by the accumulation of selectively neutral, structurally reducing mutations made possible by the lack of stabilizing selection. In a modern context, theories that account for regressive evolution in subterranean cave animals are classified into two groups: those that involve natural selection directly or indirectly and those that involve neutral mutation and genetic drift (Wilkens *et al.*, 2000).

One of the best-studied organisms in this regard is the amphipod *Gammarus minus* which occurs in springs and caves in much of the central Appalachians in West Virginia and Virginia. Populations independently isolated in caves show a strongly convergent morphology of appendage elongation and eye and pigment reduction. There was a strong correlation between the fitness components of mating and egg number with relative appendage length and eye size. Furthermore, this correlation was opposite for cave and spring populations. However, natural selection is not the whole explanation for eye and pigment reduction in *G. minus*. The rate of change of reduced structures is consistently greater by an order of magnitude than the rate of change of elaborated structures (Table 2). Elaborated structures changed as a result of natural selection, whereas reduced structures changed as a result of both natural selection and the accumulation of structurally reducing, selectively neutral mutations. The increased variability of eyes in recently isolated cave populations is also most easily explained as a result of neutral mutation.

The genetics of eye loss are best understood in the Mexican cave fish *Astyanax mexicanus*. Like *G. minus*, it has apparently been isolated in caves for less than 1 My. Cave populations show, relative to surface-dwelling populations, greatly reduced eyes, reduced pigment, reduced optic tecta, and increased jaw

Table 1 Morphological, ecological, physiological, and behavioral adaptations to subterranean life

Morphological	Ecological and physiological	Behavioral
Reduced eyes, pigment, and wings	Reduced metabolism	Reduced aggregation
Specialization of extra-optic sensory organs	Resistance to starvation	Reduced response to alarm cues
Cuticular thinning	Reduction of circadian rhythm	Increased sensitivity to vibrations
Modification of feeding structures	Reduced egg number; increased egg volume	Reduced intraspecific aggressive behavior
Reduction of scales (fish)	Increased life span	
Elongation of appendages		

Table 2 Evolutionary rates of divergence for different morphological characters of a cave population of the amphipod *Gammarus minus* from its ancestral spring population^a

Morphological Character		Δ	Relative rate
Size	HL	4.0×10^{-7}	0.02
Eyes	EN	2.4×10^{-5}	1.00
	EA	1.5×10^{-5}	0.62
Antennae	P1	8.2×10^{-7}	0.03
	L1	4.1×10^{-7}	0.02
	N1	1.1×10^{-6}	0.05
	P2	1.1×10^{-6}	0.05
	L2	8.9×10^{-7}	0.04
	N2	1.4×10^{-6}	0.06

^aThe measure of divergence, Δ , is independent of the size of the character and depends only on its variability. The two populations compared are Organ Cave and Organ Cave spring, about 2 km apart in southern West Virginia. Time since divergence was set to 5×10^5 years. Traits were head length (HL), eye ommatidia number (EN), surface area of compound eye (EA), peduncle length of first antenna (P1), flagellar length of first antenna (L1), number of flagellar segments of first antenna (N1), and second antenna analogs (P2, L2, and N2). In the last column, all rates are compared with that of ommatidia number, which was set to 1.

size, taste bud number, and increased cranial neuromast size and number. The manner of eye development and degeneration, the ability to experimentally restore eyes by lens transplantation, and the analysis of gene expression patterns in *A. mexicanus* make it a particularly useful model for understanding the evolution of eye degeneration. Recent key discoveries are (1) the expansion of Hedgehog (*Hh*) signaling along the anterior midline, which suppresses expression of the *pax6* gene (encoding transcription factor that functions upstream in eye gene hierarchies) in the developing eye fields and (2) control of eye degeneration by Hh-mediated lens apoptosis (cell death) in cavefish embryos. William Jeffery concluded from these and other studies that the best explanation for eye degeneration in *Astyanax* cavefish is natural selection for beneficial traits that are negatively linked to eye development by pleiotropy involving the Hh signaling pathway. The roles of *Hh* and *pax6* genes are shown in Figure 3.

Among subterranean organisms, adaptations have been most thoroughly studied in cave animals. After eye and pigment reduction, the most characteristic troglomorphic traits are the elaboration or elongation of extra-optic sensory structures (Table 1). Among arthropods, the elongation of

Figure 3 (a) Diagram showing the relationship between *shh* (dark blue) and *pax6* (red) expression at the neural plate stage in cyclopic (left), surface fish (middle), and cavefish (right) embryos. (b) Model showing positive (arrows) and negative (blocked line) pleiotropic effects of *shh* signaling on constructive traits and eyes, respectively. antennae is especially noticeable. A striking example is the cave beetle *L. hohenwartii* found in the Dinaric Mountains of Italy and Slovenia (Figure 2). Vertebrates such as the North American cave fish in the Amblyopsidae display a striking hypertrophy of the lateral line system. These changes are also reflected in the central nervous system. Areas associated with vision decrease in size and areas associated with the other senses increase (Figure 4). The potential advantage of elaboration and increase in extra-optic sensory structures is to compensate for the absence of light by increasing tactile and chemical sensory sensitivity. In the resource-poor environment of caves, metabolic efficiency is often increased, particularly among species at or near the top of the food chain. Activity is often reduced, as is the metabolic rate. The frequently observed decline in intraspecific aggressive behavior of troglobionts and stygobionts may also in part be an evolutionary response to food scarcity. Food scarcity is also apparently a

Figure 4 Brain morphologies of four fishes in the family Amblyopsidae: (a) *Chologaster cornuta*, a surface-dwelling species; (b) *Forbesichthys agassizi*, a stygophile found in both springs and caves; (c) *Amblyopsis rosae*, a stygobiont; and (d) *Speoplatyrhinus poulsoni*, a stygobiont. strong selective force in life-history patterns of cave animals. Cave animals live longer, begin reproduction at a later age, produce fewer offsprings, and have larger eggs – all adaptations to a relatively constant, food-poor environment. Perhaps, the most striking example of life-history modifications is that of a population of the crayfish *Orconectes australis australis* in Shelta Cave, Alabama. In an extensive mark-recapture study lasting more than 6 years, John E Cooper found that the age at first reproduction was ~35 years, and that the crayfish lived to an age of more than 100 years (Culver, 1982).

Animals in other subterranean habitats also show many of the same adaptations since they share an aphotic, resource-poor environment, in common with cave animals. However, there are two other environmental factors that exert

Figure 5 A typical soil collembolan (*Onychiurus armatus*, left) and a highly troglomorphic collembolan (*Pseudosinella christianseni*, right). Reproduced with permission from K. A. Christiansen, Grinnell, Iowa.

strong selective pressures not present in cave environments: intragranular space size in interstitial habitats and oxygen levels in aquatic interstitial habitats. Interstitial animals tend to be both thin and small since they are constrained by interstice diameter. The morphological contrast between cave and interstitial animals can be quite striking. A terrestrial example comparing a cave- and deep-soil-dwelling Collembola is shown in Figure 5. The small size of many aquatic interstitial species may occur as a result of progenesis, which is the precocious sexual maturation of an organism resulting in an adult descendent exhibiting the juvenile morphology of its ancestor. This process also results in reduced extremities, spines, and bristles. More than cave dwellers, interstitial stygobionts must be able to survive under conditions of low oxygen. Many interstitial crustaceans are able to regulate respiration rate by varying the ventilating activity of their pleopods according to oxygen availability.

Metabolic adaptations of deep-groundwater microorganisms are just beginning to be understood. Unlike the situation with eukaryotic organisms, the basic tenet of microbial ecology, Beijerinck's principle, holds in the deep subsurface: "Everything is everywhere, the environment selects." The environment in this case is an extremely food-poor one, with little or no organic matter. The major characteristic of phreatic microorganisms is the widespread occurrence of facultative or obligate chemoautotrophy. The Gibbs-free energy available in chemoautotrophic responses is much less than that of photosynthetic organisms, reinforcing the concept of resource scarcity from a physical chemical standpoint.

Colonization and Speciation in Subterranean Environments

The terms troglobiont, stygobiont, troglophile, and stygophile are an ecological classification, which attaches great importance to the isolation of species in subterranean habitats. Troglophiles and stygophiles, species which can complete their life cycle in both surface and subterranean habitats, are often important components of cave communities. In many

cases, especially in the tropics, they outnumber troglobionts and stygobionts. Troglobionts and stygobionts are typically but by no means always troglomorphic. The evolution of troglomorphic (stygobiotic) species that are troglomorphic (stygomorphic) has received the most attention.

There are two components to evolution in subterranean habitats: colonization and subsequent isolation of the subterranean populations usually as a result of the extinction of the surface-dwelling populations. Colonization may be active or it may be passive, that is, "colonization under constraint." An example of active colonization is the movement of surface-dwelling Homoptera in lava fields in Hawaii and elsewhere into lava tubes and cracks in the lava in which root sap is an abundant resource. In some cases, speciation has proceeded without the extinction of the surface populations. The mechanism of speciation is either parapatric or sympatric. Active colonization may be particularly important for interstitial organisms, such as copepods. The classic case of colonization under constraint is that of many troglobionts in north temperate caves. Many of the surface-dwelling ancestors of these troglobionts were leaf-litter-dwelling invertebrates. During Pleistocene interglacials, as warming occurred, many of these

species were either forced into caves or up mountain slopes to cooler conditions. As warming continued, surface populations became extinct. For most cases of colonization under constraint, the factor that forced animals into caves, such as Pleistocene interglacials or the Messinian salinity crisis in the Mediterranean, was also the factor that resulted in the extinction of surface populations.

Recent molecular analysis allows a more detailed look at the biogeographic history of the surface- and cave-dwelling isopod *Asellus aquaticus*. The species itself is apparently very old, and is part of a Paratethys fauna (8–12 My) unrelated to more recent Mediterranean invaders. In the Dinaric karst in Slovenia and extreme northeast Italy, *A. aquaticus* has invaded cave systems at three separate times between 3.6 Ma and 800,000 years ago, including two colonizations of the Postojna-Planina Cave System (PPCS). The oldest lineage split is after the Messinian Salinity Crisis but before the Pleistocene. The present pattern is the result of fragmentation and migration (Figure 6).

By whatever mechanisms organisms colonize subterranean environments and by whatever geological or climatological event surface populations become isolated in subterranean environments, subsequent dispersal is generally extremely

Figure 6 Graphical representations of a hypothetical chain of events that best explains the current distribution of haplotypes of *Asellus aquaticus* in the Slovenian Dinaric karst. A zigzag line indicates fragmentation events that separated drainages. Approximate dimensions of the map are 160 × 120 km. Localities are BR, Ljubljansko Barje (ditch); CR, Cerknica Polje; KJ, Krka Cave; KO, Kočevje Polje; LB, Trebiciano Cave (Italy); RB, Ribnica Polje (spring); RI, Kočevje Polje-Rinža River; VR, Vršnica Cave; and ZB, Zbilje Reservoir (Sava River). Reproduced from Verovnik R, Sket B, and Tronteli P (2004) Phylogeography of subterranean and surface populations of water lice *Asellus aquaticus* (Crustacea: Isopoda). *Molecular Ecology* 13: 1519–1532, with permission from Wiley.

limited. Most subterranean species have very restricted ranges. For example, more than 60% of the obligate subterranean-dwelling species described from the US are known from a single county, and about half of these are known from a single locality. Species with large ranges, at least for subterranean species, have on closer examination been shown to be complexes of morphologically identical but genetically distinct species and semispecies. For example, the European cave salamander *P. anguinus* ranges more than 500 km from Italy to Montenegro but actually represents several invasions of a common surface-dwelling ancestor that is extinct. For some species, there is little gene flow at distances of less than 1 km. This makes subterranean species excellent markers of biogeographic events. Once species are isolated in subsurface habitats, which are often a refuge from the vicissitudes of surface climatic change such as temperature and salinity, their distribution may leave a record of ancient events, especially continental drift. Examples abound in the Crustacea. The distributions of the order Syncarida and the amphipod family Bogidiellidae are Pangaeen and predate the pre-Triassic breakup of Pangaea. The stygobiotic copepod genera *Rheocyclops* from North America and *Graeteriella* and *Speocyclops* from Europe are probably closely related taxa that differentiated after the breakup of Laurasia; their isolation presumably dates back to the late Mesozoic. The order Remipedia and the ostracod genus *Danielopolina* have a Tethyan distribution. The distribution of the amphipod genus *Longipodacrangonyx* in Morocco closely matches the embayments of the Eocene sea, with little movement since then (Figure 7). In most of these cases, extinction of

surface populations was a result of marine regression. Of course, not all subterranean species are as old as the examples given here, but they do indicate the apparent great age of some subterranean groups combined with highly restricted dispersal.

A final example is the remarkable cave clam, *Congerius kuscieri*, the only known stygobiotic clam. Known from a series of caves in Bosnia and Herzegovina, Croatia, and Slovenia, *C. kuscieri* is the only living representative of an otherwise extinct genus, known from the late Miocene. Marine ancestors were apparently victims of the Messinian salinity crisis 6 Ma, and *C. kuscieri* is likely a relic of Pliocene lakes and rivers in the region. As the lakes and rivers disappeared under ground, *C. kuscieri* went with them.

Some Representative Subterranean Communities

Epikarst Community in PPCS, Slovenia

Epikarst communities are best sampled by collection and filtration of drip water over extended periods of time. Animals in dripping water are the ones that have been swept out of their primary habitat above the cave passage. Direct sampling of epikarst habitats is not possible due to the small size of the cavities and their inaccessibility. The best-sampled epikarst community is that of PPCS, where 20 drips were continuously sampled for more than 1 year. The drips exhibited considerable environmental heterogeneity. Drip rate itself ranged between 1.7 and 202 ml min⁻¹ (mean = 35.3, median = 8.8). Conductivity varied between 238 and 548 $\mu\text{S cm}^{-1}$, probably

Figure 7 Localities of all known sites (stars) of *Longipodacrangonyx* amphipods plotted on a sketch map of Morocco showing the three marine embayments during the Eocene (shaded areas). Reproduced from Boutin C (1994) Phylogeny and biogeography of metacrangonyctid amphipods in North Africa. *Hydrobiologia* 287: 49–64, with permission from Springer.

reflecting different residence times of the water in the sub-surface. A total of 23 copepod species (4 Cyclopoida and 19 Harpacticoida) were found in the drips, including 8 undescribed species. Six of these 23 species are endemic to PPCS. A total of five species were in a single genus – *Bryocamptus*. Species composition was extremely heterogeneous; differences in drip rate, ceiling height, and nitrate concentrations were correlated with differences in species composition. There was also a strong distance effect, with drips closer than 100 m being more similar than those farther away. The scale of variation of epikarst communities is remarkable – even drips less than 100 m apart often have different species. This probably reflects the semi-isolated nature of the small cavities that comprise the epikarst (Figure 1).

Cave Stream Community in PPCS, Slovenia

Consisting of 17 and 6 km of passages, respectively, connected by 2 km of flooded corridors, the PPCS has more known species of stygobionts than any other cave or other subterranean site. The sinking river in the main passages is inhabited by a rich assortment of stygobionts, stygophiles, and accidental surface species. Both streams drain a catchment area of more than 100 km². Above the cave passages is the rich epikarst community. Among the 48 stygobionts is the European cave salamander *P. anguinus anguinus*. Both the snail (8 species) and crustacean (16 species) faunas are rich. The marine origin of some of the stygobiotic species is evident in the hydrozoan *Velkovrhia enigmatica* and the cirolanid isopod *Monolistra racovitzae racovitzae*. Three species of the amphipod genus *Niphargus*, as well as populations of *A. aquaticus* were isolated in the cave at different times. The Postojna-Planina Cave System is one of the best-studied caves in the world, and parts of it have been heavily visited by tourists since 1818.

Phreatic Community of Edwards Aquifer, Texas, USA

San Marcos Spring is an artesian spring that serves as an exit for the Edwards Aquifer, a large cavernous limestone reservoir that lies along the Balcones escarpment. The aquifer occupies an area of 10,000 km². Two thirds of the 27 stygobionts are crustaceans, and endemism is high as well. The subterranean amphipod fauna in this system may be the most taxonomically diverse of its kind in the world and includes 10 species of gammaridean amphipods, representing eight genera in four families. The vertebrate stygobiotic fauna is rich with two catfishes (*Satan eurystomus* and *Trogloglanis pattersoni*) and the Texas blind salamander *Typhlomolge rathbuni*. Oil and peat deposits above the aquifer as well as long-term and gradual input of organic material into the aquifer through numerous sinkholes on the adjacent Edwards Plateau are the primary inputs into the system. The aquifer is threatened by excessive draw down, both by agricultural interests and by the city of San Antonio. Lowering of the aquifer also threatens species limited to the springs of the Edwards Aquifer, including two fish (*Etheostoma fonticola* and *Gambusia georgei*) and two aquatic beetles (*Heterelmis comalensis* and *Stygoparnus comalensis*) on the US Endangered Species List.

Anchialine Community of Walsingham Caves, Bermuda

This complex of anchialine caves (ones with a direct connection to the sea) is ~1 km long, with most of the passages submerged. With a freshwater lens and a redox boundary between fresh and saltwater, Walsingham Cave likely has considerable productivity as the result of chemoautotrophic and heterotrophic production. The fauna is entirely aquatic, with 37 species, 29 of which are crustaceans. Among the crustaceans is a representative of the exclusively subterranean order Mictacea and rich ostracod and copepod faunas with six species each.

Spring Community of Organ Cave Resurgence, West Virginia, USA

Organ Cave is a large, complex cave aligned along the axis of a minor syncline and has more than 40 km of surveyed passages, most of which have permanent streams. The cave waters with a catchment area of ~15 km² drain at a single resurgence, which empties directly in Second Creek. Base-level discharge is about 125 l s⁻¹. As is typical of large karst springs, environmental conditions (temperature, chemistry, etc.) are very stable, and the water resurging at the spring has been underground at least as long as the cave water, in this case typically 3–6 days. A total of 19 macroscopic invertebrate and two fish species have been found in the cave. Only four of these species have been found in the spring. Of these, three are rare stygophiles (a snail, a stone fly, and an amphipod). The fourth, *G. minus*, is a genetically and morphologically distinct population from that of the cave. This separation is remarkable, given that the cave has been explored to within 1 km of the resurgence. The remaining 1 km is probably a water- and sediment-filled tube.

Hygropetric Community of Vjetrenica, Bosnia and Herzegovina

Vjetrenica is a moderately sized (8 km) cave on the edge of Popovo Polje about 20 km from the Adriatic Sea. It has very diverse aquatic habitats including a 180 m long lake (Veliko Jezero) and hygropetric habitats. Thin sheets of permanently flowing water over vertical rock make up the hygropetric habitat. Two species of Coleoptera in the subfamily Leptodirinae (*Hadesia vasiceki vasiceki* and *Nauticiella stygiva*) are specialists in the hygropetric, apparently filter feeders. Other species, both aquatic (the amphipod *Typhlogammarus mrazeki*) and terrestrial (the isopod *Aspioniscus*) are often found there as well. In general, the cave has a very rich stygobiotic and troglobiotic fauna (see Table 3).

Chemoautotrophic Community of Movile Cave, Romania

Movile is a small (<300 m), mostly water-filled cave near the coast of the Black Sea with no natural connection to the surface. Extensive chemoautotrophic production in the form of sulfur oxidation occurs in the cave system. Eighteen stygobionts are known from the cave, and the chemoautotrophic production also supports a terrestrial community of 27 troglobionts. About two-thirds of the fauna is endemic to the

Table 3 Caves with more than 25 stygobionts (A) or 25 troglobionts (B). Data compiled from various sources (see Culver and Pipan 2009)

cave or groundwater system that the cave intersects. Among the unusual components of the fauna are an endemic leech and an endemic water scorpion (*Nepa anophthalma*). Based on analysis of mitochondrial DNA sequences, *N. anophthalma* was isolated in the cave 2 Ma. The high diversity is made possible by the high productivity, and the high endemism is a result of the lack of contact with the surface.

Communities in Groundwater Calcretes, Western Australia

In arid Western Australia, a series of shallow aquifers of Oligocene age, formed by groundwater near the surface, have been colonized by a remarkable variety of stygobionts, including diving beetles, amphipods (Crangonyctoidea and Melitoidea), and isopods (Phreatoidea). Aside from organic matter in percolating water, tree roots that penetrate the calcrete are an important food source. Although regional diversity is high, overlap among related species is low, and different isolated calcretes have different but related species. The fauna was probably isolated in these calcretes during the drying periods of the Tertiary.

Interstitial Communities in Lobau Wetlands, Austria

Formed by a meander arm, the Lobau wetlands are part of the floodplain of the Danube River near Vienna. Extensive studies of the superficial gravel sediments, which are up to 20 m thick, using pumps and minivideo cameras in shallow wells revealed a complex habitat with areas of differing oxygen and permeability and a rich fauna. In a 1 km² area, more than 100 species were found, one third of which were stygobionts. Stygobionts were more common at depths of greater than 5 and 100 m away from surface water. The microcrustaceans – Copepoda and Ostracoda – were particularly diverse.

Interstitial Communities of Rhone River, France

After the Danube, the Rhone River is the most thoroughly studied river with respect to its interstitial fauna. Thirty-eight stygobiotic species, dominated by 23 crustaceans and 10 oligochaetes, have been found in the interstitial waters of the Rhone. There are considerable faunal differences depending on the distance from the main channel of the river, depth, and upwelling and downwelling.

Hypotelminorheic Communities of Rock Creek, District of Columbia, USA

Rock Creek is a small urban stream in the metropolitan Washington, DC, area. Most of the stream and a substantial portion of the watershed is in parkland. Small seeps, with catchment areas usually less than 0.01 km² and underlain by clays at a depth of 25–50 cm, occur along the banks of the creek, usually 20–50 m above the stream. Five species of the amphipod genus *Stygobromus* as well as the isopod *Caecidotea kenki*, and the snail *Fontigens bottimeri* are found in these seeps. Compared with other subterranean habitats, organic material is abundant and all of the seeps are lined with dead and decaying leaves. Most, if not all of the seeps, dry up at least occasionally and animals likely survive by burrowing into the clay layer.

Terrestrial Community of Gua Salukkan Kallang-Towakkalak, Indonesia

This immense river cave system, with more than 20 km of passage and a large bat population, is unusual among lowland tropical caves in the richness of its troglomorphic fauna. Food resources are abundant in the cave. There are large amounts of flood debris along the riverbanks, and bat and swiftlet guano is scattered along the underground galleries. In addition to

troglobionts, there are many species specialized on guano as well. Arachnids and Collembola dominate the 21 troglotic species.

Terrestrial Community of Mammoth Cave, Kentucky, USA

The longest cave in the world with more than 500 km of passage, Mammoth Cave harbors 28 troglotic species. Most of the cave lies within the boundaries of Mammoth Cave National Park. The long length of the cave is due in part to a sandstone caprock that reduces erosion and loss of upper-level passages. In the large upper-level passages with sandy-bottomed floors (an unusual cave habitat), troglotic cave crickets (*Hadenocercus subterraneus*) deposit their eggs. Since *H. subterraneus* regularly leave the cave to feed, their eggs are an important energy source for beetles. Predaceous beetles, *Neaphaenops tellkampfi*, specialize in predation on cricket eggs. Such specialization is unusual because of the scarcity of resources in most caves. Also noteworthy is the co-occurrence of five species of trechine beetles in the closely related genera *Neaphaenops* and *Pseudanophthalmus*.

MSS Communities of Ariège, France

The MSS is a subterranean habitat that occurs typically in mountainous regions in deposits of scree not infilled by soil. In its structure, it bears some resemblance to dry epikarst. Communities are similar to nearby terrestrial cave communities, but with some species unique to the MSS. Among these are the cholevid beetles such as *Speonomus colluvii* and *Mehadiella paveli*. The majority of species, both troglotrophs and troglotic species, are found in both caves and the MSS – arachnids, beetles, and Collembola.

Terrestrial Epikarst Communities of Organ Cave, West Virginia, USA

In a sampling of 13 drips in Organ Cave for a period of 30 days, 176 terrestrial arthropods were collected in dripping water, indicating an abundant arthropod fauna in the epikarst. Nearly all of these individuals, except for a few troglotic Collembola, were troglotrophs. Epikarst communities in general have been little studied.

Terrestrial Communities of Vjetrenica, Bosnia and Herzegovina

Vjetrenica is a moderately sized (8 km) cave on the edge of Popovo Polje. It is one of the most faunistically rich caves in the world (see Table 3) largely due to its geographic position and ecological heterogeneity. The terrestrial fauna of 30 troglotic species depends on food brought in by moving water, and to a much lesser extent by animals moving in and out of the cave. The most common species in the main corridor is *Antroherpon apfelbecki*. Some species have very restricted distributions within the cave; for example, the centipede *Typhloglomeris caeca* is limited to large clay deposits.

Terrestrial Lava Tube Community of Kazumura Cave, Hawaii, USA

Located on the island of Hawaii, it is the longest lava tube in the world, more than 60 km long, covering a straight line distance of 32.2 km, and a vertical extent of more than 1000 m. Delicate tree roots penetrate the thin soils and lava, and provide a food source for the terrestrial fauna. Among the species feeding on the roots are a cixiid plant hopper, *Oliarus polyphemus*, a noctuid moth in the genus *Schrankia*, and a gryllid cricket, *Caecomobius varius*. It is noteworthy for both the main food source and the unusual species (at least for subterranean habitats).

Bat Colony of Bracken Cave, Texas, USA

More than 20 million Mexican free-tailed bats (*T. brasiliensis*) form the largest known bat maternity colony in the world, producing millions of young each year. It is one of the largest, if not the largest, concentrations of vertebrate biomass. About 30 km from downtown San Antonio, it is protected by Bat Conservation International. The concentration is large enough to substantially increase the temperature of the roost environment.

Geography of Cave Biodiversity

Although other subsurface habitats have not been sufficiently studied to analyze biogeographical patterns, caves have been. On a worldwide basis, more than 10,000 caves have been biologically investigated, and there is an extensive amount of information about the number of troglotic species and troglotic species at individual caves and karst wells. Because of the restricted possibilities for dispersal and the restricted abilities of troglotic species and troglotic species to disperse, species numbers in any one cave or karst well are low relative to the regional fauna. On a worldwide basis, there are not sufficient data to analyze regional faunas of similar areas, but there are enough data to analyze the geographic pattern of fauna-rich caves.

The nine caves and karst aquifers with more than 25 troglotic species are listed in Table 3a. In this case, a strong

Table 4 Species richness of epikarst copepods in well-sampled caves

Cave	Country	Total number of Copepods	Number of Stygobiotic Copepods
Velika Pasica	Slovenia	12	9
Postojna-Planina Cave System	Slovenia	23	16
Škocjanske Jame	Slovenia	17	10
Dimnice	Slovenia	12	11
Županova Jama	Slovenia	16	14
Organ Cave	US	10	7

Figure 8 (a) Map of species richness patterns of North American troglobionts. Major karst areas of eastern and central US are shown in light gray. Although there are many caves in the western United States and Canada, there are no large karst areas, and no areas of rich fauna. The open triangles are areas with few if any troglobionts, the gray triangles are areas with less than 50 species, usually much less than 50. The three open circles are three areas analyzed in this study with less than 50 species in 5000 km² of area or less. The black circle is the diversity hotspot in northeast Alabama. The boundary of the Pleistocene ice sheet is shown as a solid line. A pair of dashed lines indicates the hypothesized position of the high-diversity ridge. (b) Map of species richness patterns of European troglobionts. The open triangles are areas with few if any troglobionts, the gray triangles are areas with less than 50 species, usually much less than 50, and the gray circle is Ardeche, with less than 50 species in 5000 km² of area or less. The black circles are the diversity hotspots in Slovenia and Ariege. Black triangles are other possible diversity hotspots. The boundary of the Pleistocene ice sheet is shown as a scored solid line. A pair of dashed lines indicates the hypothesized position of the high-diversity ridge. Adapted from Culver DC, Deharveng L, Bedos A, *et al.* (2006) The mid-Latitude biodiversity ridge in terrestrial cave fauna. *Ecography* 29: 1, 120–128.

geographical component is evident. More than half of the caves are in the Dinarides. The Dinaric karst has two unique features – it is adjacent to the Mediterranean Sea and karst development as measured by cave passage density is higher than elsewhere. Adjacency to the Mediterranean afforded opportunities for invasion of marine taxa during periods of drying, such as the Messinian salinity crisis. The remaining cases, with one exception, are entirely phreatic or with major phreatic components. The exception is Walsingham Cave in Bermuda, a high-energy anchialine cave. Thus, the mark of history is obvious with the predominance of examples from one geographic region – the Dinaric karst. The reason that phreatic habitats are so well represented is less clear but it may be that the contiguous area of these aquifers is much greater than the contiguous areas of other aquatic subterranean habitats.

The seven caves with more than 25 troglobionts are listed in Table 3b. Both ecological and geographic components are evident. The ecological component is that high-productivity caves, those in Canary Islands very close to the surface (three caves) and caves with high chemoautotrophy (one cave), are well represented. For the remaining caves, two are in the Dinarides. The exception is Mammoth Cave in the US, which is aberrant because of its great length (> 500 km), much longer than any other limestone cave. The caves in the Dinarides are also in karst regions of Europe with high secondary productivity. Thus, both productivity and history play a role.

Not included in the above analysis is the fauna of epikarst. Epikarst in only a handful of caves has been sampled but it is clear from these results that the richness of epikarst stygobionts may rival that of the stygobiotic fauna in other subterranean aquatic habitats (Table 4). In the six caves in which the epikarst has been extensively sampled, the number of stygobiotic copepods ranged between 7 and 16! In several of these caves (e.g., Organ Cave, Županova Jama, and Škocjanske Jame), stygobiotic epikarst copepod species outnumber all other stygobionts known from the particular cave. The potential for discovery of new species in epikarst is enormous.

Although there are insufficient data for a global comparison of species richness by region, there are considerable data available for Europe and North America (Figure 8). When extensively sampled cave regions of between 2000 and 5600 km² are compared, a ridge (~42–46° in Europe and 34° in North America) of high biodiversity occurs in temperate areas of high productivity and cave density. As was the case with individual caves of high troglobiotic diversity, the pattern reflects a strong dependence of terrestrial cave communities on long-term surface productivity (as reflected in actual evapotranspiration). This dependence may explain the unique biodiversity pattern of terrestrial cave invertebrates.

Conservation and Protection of Subterranean Habitats

Subterranean sites present special conservation and protection problems. Literally out of sight, they are often neglected in

decisions concerning conservation priorities. When they are considered, the high levels of endemism make it difficult to set priorities among endemic species. Once the decision has been made to protect cave and other subsurface sites, several principles apply. The protection of bat sites is most effectively done by gating the cave. However, there is considerable risk to the bats if the gate is not properly designed. Improperly designed gates can change environmental conditions in the cave, making it unsuitable for bats, and if the bars on the gate are not properly spaced bats can suffer considerable predation at the gate. Second, protection of the subterranean aquatic fauna requires protection of the surface riparian habitat. In the case of cave streams, their upstream sources, whether they are sinking streams or sinkholes, must be protected. In the case of epikarst species, it is the surface immediately above the cave that must be protected. Similar protection schemes are needed for the terrestrial riparian fauna. Third, protection of deep-groundwater species requires protection from both excessive draw down and contamination of the aquifer. Fourth, protection of troglobionts that rely on the flow of organic matter into the cave entrance, such as those *Neaphaenops* beetles that are predators of cricket eggs, must include protection of the entrance area and any foraging area of the species responsible for bringing organic matter into the cave. Finally, conservation and protection of subsurface sites requires greater public awareness and appreciation.

Glossary

Biome A group of ecosystems which are subject to similar climatic conditions and which share a similar range of vegetation structures, animal diversity, and soil types.

Biomes represent major regional groupings of ecological systems and are therefore discernible at the global scale.

Ecosystem All of the organisms living within or utilizing a particular area, together with their surrounding nonliving environment.

Ecosystem classification A procedure for grouping together similar ecosystems based on a predefined set of criteria, e.g., vegetation structure, climate, land-use history, and soil type.

Latitudinal biodiversity gradient The well-documented trend for there to be more species in tropical ecosystems compared with temperate or polar ecosystems.

The Earth's Terrestrial Ecosystems

Ecosystem Classifications: Overview

Terrestrial ecosystems cover approximately 148 million km², corresponding to 29% of the total surface area of the earth. They include such diverse habitats as the frigid regions around the poles, the searing heat of tropical deserts, and lush temperate and tropical rainforests. This enormous variety poses great difficulties for the study of ecosystems at regional to global scales, and it has led to the development of many classification systems which seek to reduce this complexity to a manageable level. Indeed, the development of such classification systems, and the identification of the spatial extent of the Earth's major ecosystem types, is a fundamental first step in managing the world's biological systems.

Despite the importance of this problem, the classification of the world's ecosystems into a consistent and useable framework is not without its problems. First, ecosystems usually grade into one another, hence making it difficult to mark ecosystem boundaries on a map. Second, there is no single agreed upon definition of an "ecosystem." To some researchers it represents an area within which the same broad mix of species can be found. To others it is merely an arbitrary area delimited solely for practical purposes. Third, different criteria can be used to generate different kinds of classifications. For example, human-induced land-use change is included in some classifications but not in others. Ecosystem classification systems are therefore approximations of reality and should be viewed as a set of tools which provide a simplified overview of the relative extents and spatial arrangements of the world's major ecosystem types.

Ecosystems are usually classified according to the dominant vegetation type for a region, which is in turn determined largely by geographical and environmental factors. Vegetation is considered the most appropriate criteria for classifying ecosystems because it constitutes the majority of biomass and also because of its role, through the process of photosynthesis, as the primary fixer of energy on which all other life depends.

The Biome Classification

The broadest units of ecosystem classification are called biomes. Biomes are complex mixtures of a large number of similar ecosystem types which share a similar physiognomy (vegetation structure) and climate but do not necessarily share the same species. Indeed, one of the strengths of the biome approach is that ecosystems with different species compositions, but with similar vegetation structures and ecosystem processes, can be compared. For example, the tropical rainforests of Central America and northern Australia are both recognized as belonging to the same biome "tropical rainforest," even though there would be little overlap in species composition between the two regions. The major climatic variables on which the biome classification is based are average annual temperature and average annual precipitation.

Many biome classifications have been suggested. These have classified the world into as little as 8 and into as many as 18 separate biomes. **Figure 1** shows the classification of Cox and Moore, which maps 10 major terrestrial biomes. One feature of the spatial distribution of the world's biomes is that many are fragmented over the surface of the earth. For example, the "Mediterranean" biome is found in the areas surrounding the Mediterranean sea and also in Australia, South Africa, South America, and North America.

A brief description of the major terrestrial biomes is given in the following sections. More complete accounts of each can be found in the appropriate sections of this encyclopedia.

Tundra

Tundra occurs around the Arctic Circle at latitudes above where trees can survive and also at high altitudes above the tree line in other regions. The vegetation is of a very low stature, typically comprising low shrubs, sedges, grasses, lichens, and mosses. The climate is characterized by long, cold winters, during which average monthly temperatures seldom exceed 0 °C and, at the highest latitudes, there is constant darkness for weeks at a time. Soils are permanently frozen (permafrost), making water unavailable to plant growth.

Figure 1 The world's major biomes, based on the classification of Cox CB and Moore PD (1985) *Biogeography. An Ecological and Evolutionary Approach*. Oxford: Blackwell, with permission from Wiley.

Also, liquid water is available for only short periods at a time, thus making these ecosystems effectively "polar deserts." Due to these harsh climatic conditions and brief growing season (usually less than 60 days), plant growth and decomposition is slow and ecosystems are very slow to recover from disturbance. Animal diversity is similarly low, with a small number of permanent bird and mammal species and a number of seasonal insects. Many bird species and some mammals migrate to the tundra during the brief summer.

Taiga (Boreal Forest and Northern Coniferous Forest)

The taiga forms a broad band adjacent to the tundra biome, extending across North America, northern Europe, and northern Asia. The dominant vegetation consists of evergreen conifers, with some representation of deciduous broadleaved species in some environments. Within this biome it is common to find large areas of land dominated by only one or a few coniferous tree species. Winters are typically long and cold, contrasting with summers that, although brief, can be both warm and wet. The soils are characterized as being nutrient poor and acidic. Characteristic animals include insect- and seed-eating birds, small mammal herbivores such as the snowshoe hare, larger browsers such as elk and moose, and carnivorous mammals such as the lynx, wolf, and grizzly bear. Many bird species migrate to the taiga during the summer to feed on swarms of seasonally breeding insects.

Temperate Forests

The temperate forest biome includes a wide range of forest types, including the temperate rainforests of the Pacific Coast of North America, southern Chile, and New Zealand; the

temperate deciduous forests of eastern North America, eastern Asia, and Europe; and temperate evergreen forests such as the sclerophyllous eucalyptus forests of Australia and the southern beech forests of Chile and New Zealand. The forest structure is generally well developed, with various strata including emergent trees, canopy trees, small trees, shrubs, and a herbaceous layer. Along with an enhanced diversity of plant species and habitat structure, there is an associated general increase in the diversity of the fauna. The growing season is approximately 6 months. Because of the wide range of forest types and environments represented in this biome, soil nutrition, precipitation, and water availability are also highly variable.

Tropical and Temperate Grasslands

The grassland biome includes ecosystems from a wide range of geographical regions and environments. In the tropics these include the savanna, which can also be associated with an open cover of shrubs or trees. Examples of temperate grasslands can be found in North America (prairies), Europe and Asia (steppe), South America (pampas), and South Africa (veld). A common feature is the importance of herbivory, particularly in the savanna, which has a high diversity of ungulate browsers. In comparison with tropical grasslands, temperate grasslands support a much lower faunal diversity. Fires are also an important component in many grassland ecosystems, in which repeated fires can prevent the establishment of woody species, thus preventing the grasslands from developing into shrublands or forests. Climate and soils vary with grassland type and region, with the tropical savanna experiencing distinct wet and dry seasons and temperate grasslands experiencing cold winters and hot summers.

Mediterranean Vegetation (Chaparral)

Examples of the Mediterranean biome can be found between approximately 30° and 40° latitude in both hemispheres and are associated with wet winters and dry summers. Mediterranean vegetation occurs most extensively on the coast surrounding the Mediterranean Sea, but it is also found as the “chaparral” in California and northwest Mexico, the “matorral” in Chile, the “fynbos” around the Cape of South Africa, and also in the southern regions of Australia. Because precipitation in this biome is generally less than in grasslands, and there are regular periods of drought, the vegetation is characterized by shrubs and small trees which have small, leathery “sclerophyllous” leaves adapted to drought stress. Fire is also a common feature of Mediterranean vegetation, and many plant species share adaptations to persist under a regime of repeated fire, e.g., resprouting from belowground and seeds that require fire to germinate. In general, soils are nutrient poor. One striking feature of this biome is that high levels of endemism are common, but adaptations to the Mediterranean environment in geographically separate regions are very similar. This has been seen as evidence for convergent evolution, in which plant and animal species from different taxonomic groups respond independently, but similarly, in response to the same environmental pressures.

Deserts

Deserts occur in climates characterized by extreme aridity. Water limitation in these areas can arise due to many factors, for example, being located in hot tropical regions in which evaporation exceeds precipitation such as the Sahara desert; rainshadow regions in which the presence of a mountain range influences precipitation patterns, resulting in dry conditions on the leeward side of the range, such as in the Patagonian desert in Argentina; and coastal deserts in which prevailing winds prevent precipitation occurring, such as in the Namib desert in southern Africa. Continental-scale effects can also be important, where the interiors of major continents are too distant from moist airflow to receive sufficient rainfall. Vegetation in deserts is sparse, with shrubs being the most common life-form. Deserts are also characterized by succulents (e.g., cacti) and many ephemeral annual and perennial species which have dormancy as some part of their life cycle, enabling them to actively grow and reproduce when rain does occur. The animals of desert regions have also evolved in response to the harsh conditions. Examples include nocturnal activity to avoid the heat of day and dormancy during the periods between rainfall events.

Tropical Forests

This biome includes tropical seasonal forests, which occur in humid tropical climates with a pronounced dry season, as well as tropical rainforests. Tropical seasonal forests are characterized by a mix of evergreen and deciduous species, with some forest types dominated solely by deciduous species. In contrast, tropical rainforest thrives in regions in which rainfall is abundant and evenly distributed throughout the year and temperatures are uniformly warm. Tropical rainforests are noted for supporting the highest recorded diversities of both plants and animals. The soils of tropical forests are typically nutrient poor, with decomposition being rapid and with the nutrients stored mostly within the plant biomass.

Other Classification Systems

Although large-scale “biome” classification systems are useful in gaining an appreciation of the spatial extent of the world’s major ecosystem types, for many applications a finer resolution is often required. Two approaches which aim to increase the detail but still retain a manageable number of categories are considered.

First, Olson’s classification is an attempt to map the world’s ecosystems as they were in 1980. Included in the classification are natural or seminatural ecosystems (e.g., “Tundra” and “Tropical dry forests”) as well as those ecosystems that have undergone human modification (e.g., “Warm crops” and “Paddyland”). Olson’s classification recognizes 44 different ecosystem complexes compared with the 10 major biomes in **Figure 1**.

A different approach was adopted by Holdridge in his “life zone” classification. This classification aims to predict the potential vegetation that an area could support rather than what ecosystems might actually be occurring there. The classification is based on two main variables, labeled “Biotemperature” and “Annual precipitation.” Annual precipitation is the average annual amount of rainfall a region receives, without taking into account its seasonal pattern. Biotemperature is the average annual temperature, excluding temperatures below 0 °C and above 30 °C. Note that these two climatic variables are essentially the same as those used to define the biomes discussed previously. A third variable in the Holdridge classification, “Potential evapotranspiration ratio,” combines precipitation and biotemperature into an index which summarizes the water availability for a particular region and quantifies the balance between the amount of water entering the system through precipitation and that lost through the combined processes of evaporation and transpiration. Evaporation is the physical process whereby water is returned directly to the atmosphere from plant and soil surfaces, and its rate is directly influenced by the amount of incoming solar radiation. Transpiration is the biological process whereby soil water is taken up by plant roots, transported through the plant’s vascular systems, and evaporated from the leaf surfaces through pores called stomata. Potential evapotranspiration ratios less than 1.0 indicate an excess of water in the ecosystem, and ratios greater than 1.0 indicate a deficit.

The classification produces 38 major life zone categories, ranging from hot-wet tropical forests and hot-dry temperate and tropical deserts to cold-dry polar deserts (**Figure 4**).

The Holdridge classification has been used in global vegetation models to predict major changes in ecosystems types in response to global climate change, and Olson’s classification has been similarly used to model the effects of global change, and in particular the dynamics of the global carbon cycle and carbon storage.

Global Patterns of Biodiversity Across Terrestrial Ecosystems

Description of Known Patterns

One of the best documented patterns of biodiversity is the tendency for tropical ecosystems to harbor more species than

temperate or polar ecosystems, i.e., there is a gradient in diversity stretching from lower latitudes (high diversity) to higher latitudes (low diversity). Some examples of different terrestrial organisms which show this pattern are shown in **Figure 2**. The trend is also seen in a wide range of marine organisms.

It is worth noting that these examples include only a subset of the total biodiversity for any given region, e.g., land-breeding birds or swallowtail butterflies. Furthermore, none of these examples are global in extent, with two of the four (landbirds and mammalian quadrupeds) being based on data from only a single continent.

The reason for the focus on small groups of species, at subglobal scales, is simply because the data required to

perform global-scale, multispecies studies of biodiversity are still incomplete. Nevertheless, despite some minor exceptions, the majority of studies that have investigated latitudinal trends in diversity have shown that tropical regions are indeed characterized by high levels of species diversity.

Although distributional information for groups of individual species at the global level is in general poorly known, that for the higher taxonomic groupings (e.g., families) is considered more complete. One example of this approach, compiled by Williams and coworkers, is shown in **Figure 3**. It shows the global distribution of the combined number of families of flowering plants, amphibians, reptiles, and mammals. Together, these four groups of families are considered to

Figure 2 Examples of the latitudinal gradient in diversity, showing higher species richness near the equator (0° latitude) for all species groups. Swallowtail butterfly data redrawn from Sutton and Collins (1991). Land bird data-points represent diversity within areas approximately 230,000 km² (MacArthur RH and Wilson EO (1967)). Mammalian quadruped data-points represent average diversity within areas approximately 62,500 km² (Rosenzweig ML (1995)). Forest tree data-points represent diversity within 0.1 ha plots (Gentry AH (1988)).

Figure 3 The global distribution of the combined family richness of flowering plants, amphibians, reptiles, and mammals (Reproduced from Williams PH, Gaston KJ, and Humphries CJ (1997) Mapping biodiversity value worldwide: Combining higher-taxon richness from different groups. *Proc. R. Soc. London B* 264: 141–148.). Grid cells are approximately 611,000 km².

be the most completely known. It has been estimated that for the chordates 90% of all living species have been identified and for plants 84.4%. These values are far in excess of any other taxonomic group. **Figure 3** shows that the trends at the family taxonomic level mirror those of individual species, with a concentration of families in the tropics, particularly around Central America and Southeast Asia, decreasing toward the higher latitudes in each hemisphere.

Figure 4 shows the relationship between the distribution of the family richnesses in **Figure 3** relative to the life zone classification of Holdridge. There is a consistent pattern, with warm/wet tropical ecosystems containing many more families than either the hot-dry (desert) or cold-wet (polar) ecosystems. Incorporating the spatial information of **Figure 3** into the Holdridge classification allows the trends in family richness across different ecosystem types to be displayed visually. The advantage of this approach, over traditional richness vs latitude relationships, is that different ecosystem types occurring at the same latitude but with different richnesses are able to be separated. For example, tropical rainforests and the Sahara desert both occur at tropical latitudes, but the latter is conspicuously lower in diversity.

A second major trend in terrestrial biodiversity is a decrease in diversity with increasing altitude. As altitude increases there is an associated change in the environment that is analogous to the changes that occur when moving from tropical to temperate latitudes. For example, temperature decreases with increasing altitude, and the total land surface area also tends to decrease with altitude (simply because mountains tend to be broader at the base than at the peaks). Because these

changes appear to mirror those observed in the tropical to temperate gradient, many researchers have suggested that the factors controlling the pattern of lower diversity at higher altitudes are likely to be the same as those controlling the latitudinal gradient.

Possible Explanations

Although many plausible hypotheses have been suggested to explain the observed latitudinal trend in diversity, many of them have proved to be controversial and there is no consensus on which of the explanations, if any, are of primary importance in determining actual diversity gradients. A major source of the difficulty is that most of the explanations are based on correlative evidence, and it is well-known that correlation does not necessarily imply causation. Correlative evidence predominates because appropriate experimental tests are extremely difficult to devise at the spatial and temporal scales required.

For any given area on the earth, the number of species present (*S*) is due to many processes acting over a range of spatial and temporal scales. These processes can be summarized into three broad categories and combined into the following simple formula:

$$\begin{aligned}
 S = & \text{species which have immigrated from outside the area} \\
 & (\text{dispersal}) \\
 & + \text{species which have arisen through speciation} \\
 & - \text{species which have been lost due to extinction.}
 \end{aligned}$$

Figure 4 The global distributions of combined family richness incorporated into the Holdridge classification, which predicts 38 vegetation types based on the climatic variables 'biotemperature' and 'annual precipitation', as explained in the text. The scale is average combined family richness (flowering plants, amphibians, reptiles, and mammals) per 611,000 km² grid cell calculated for each of the major life zones. Reproduced with permission from Rosenzweig ML (1995) *Species Diversity in Space and Time*. Cambridge, UK: Cambridge Univ. Press.

At large spatial scales (e.g., regional or between biome), dispersal can be considered of limited importance compared with speciation or extinction. Therefore, the hypotheses which aim to explain the latitudinal gradient in diversity must have, as a basis, processes which enhance speciation rates and/or reduce extinction rates in the tropics or, alternatively, which reduce speciation rates at higher latitudes and/or increase extinction at those latitudes. The hypotheses that have been suggested to explain the enhanced diversity of the tropics are described within this broad framework.

Time

One of the earliest explanations for the latitudinal diversity gradient is that tropical regions are more ancient, and therefore less disturbed, than their temperate counterparts. The greater age of the tropics implies that there has been more time for speciation to occur, hence a longer time for species to accumulate. Particular emphasis was placed on glaciations because it was assumed that temperate regions are impacted upon by glacial activity more so than the tropics. However, the fossil record does not support this view. For example, there is evidence that the latitudinal gradient for angiosperms has existed for at least 110 million years. There is also evidence that

during the most recent glaciation both temperate and tropical forests decreased substantially, with tropical forests being replaced by grassland and savanna. This suggests that tropical regions may not be as ancient or stable as once thought.

However, if the tropical rainforest remnants were more numerous, and their destruction less complete than in the temperate zone, then this continual isolation and reforming of tropical communities might promote diversity through the mechanism of allopatric speciation. Allopatric speciation is considered by many to be the most important of the speciation-promoting mechanisms. It occurs when a geographical barrier subdivides a population, such that dispersal and genetic exchange between the subpopulations is prevented. These sub-populations continue to evolve in isolation, eventually diverging enough so that two new species are produced. In this scenario, higher diversity in the tropics might be promoted due to enhanced allopatric speciation due to historical geological events, possibly combined with an increased extinction rate in the temperate regions.

Area

Calculated on a land area basis, tropical and subtropical ecosystems are approximately five times more extensive than

temperate ecosystems and approximately twice as extensive as boreal and tundra ecosystems. The reason is due to the earth being approximately spherical so that a zone of a constant width running around the equator (the tropics) will contain much more area than a zone of equivalent width running around the earth's surface closer to the poles. Therefore, tropical ecosystems, which contain the highest diversities, are also those which cover the largest land area.

Rosenzweig suggested three reasons why a greater land area in the tropics might result in greater diversity. They are all based on the assumption that the geographical ranges of tropical species are, or were in the past, larger than the ranges of species in other latitudes. First, a larger geographical range leads to a larger total population size, and a larger population size would be expected to buffer the species against accidental extinction. Second, a larger geographical range contains a greater number of potential refuges where the species might survive following catastrophic disturbances or climatic events, again buffering the species against accidental extinction. Third, a larger range has more chance of being subdivided by a geographical barrier, hence increasing the probability of allopatric speciation.

Habitat Heterogeneity

All other things being equal, larger areas also contain a greater variety of habitats than smaller areas, and hence they are capable of supporting more species, i.e., there is opportunity for the evolution of species to fill these available habitats. Because tropical ecosystems tend to be larger in extent than those in other regions, it follows that they should contain a greater number of species.

It has also been suggested that the increase in the diversity and complexity of vegetation as one approaches the tropics can enhance diversity by providing animals with a greater variety of arboreal habitats. This increased faunal diversity can enhance diversity because many of these species can become a resource on which species higher in the food chain can be supported. Although the increased vegetation complexity in the tropics potentially explains the increased diversity in animal species, it cannot explain the high plant diversity because there is no evidence to suggest that plant habitats are more diverse in tropical regions.

Despite many studies which illustrate a positive relationship between habitat heterogeneity and diversity, care must be taken with the interpretation of these results because habitats are often defined by the species that occur within them, hence leading to circular reasoning. To be a valid hypothesis, habitat heterogeneity must be defined independently from the species occupying those habitats.

Solar Energy

Tropical regions receive, per unit area and per unit time, greater amounts of solar radiation than any other ecosystems. This is again due to a spherical Earth, whereby light energy at higher latitudes intercepts the earth's surface at a more oblique angle compared with the tropics. Although the amount of incoming solar radiation directly affects productivity, and relatedly, the water balance of a region, it also has the potential to accelerate the rate at which new species evolve.

An acceleration of the evolutionary process in tropical regions can arise due to two factors. First, the greater amount of available energy might explain the tendency for tropical species to have shorter generation times. A shorter generation time means more offspring per unit time, hence faster evolution. Second, increased solar radiation would be expected to increase mutation rates, thereby increasing the genetic variability on which natural selection acts, leading to an increase in the rate of speciation. These two factors combine so that over evolutionary time more species would be expected to have evolved in tropical regions rather than those at higher latitudes.

Species Interactions

Species interactions, and in particular competition, are central to many hypotheses addressing the latitudinal diversity gradient. A common ingredient to these hypotheses is that there are factors in the tropics which allow competitive exclusion to be avoided or which allow shifts in the "ecological niche" of a species so that competition is no longer intense, enabling the coexistence of many species. The ecological niche is a multi-dimensional summary of the environmental ranges and resource tolerances of a species. Species with broad niches are considered generalists, and species with narrow niches are considered specialists. Most important, the amount of niche overlap between species is a measure of the amount of competition experienced. For example, two species with overlapping niches require the same range of resources and environmental conditions; hence, they would be expected to compete strongly, and in the absence of any other factors the weaker competitor of the pair would be expected to be eliminated by the stronger. This is known as the "competitive exclusion principle."

It has been suggested that competition between species in the tropics is of greater importance, and is potentially more intense, than that in temperate regions. The reason given is that the tropical environment is more predictable and less prone to large disturbance events which cause indiscriminate mortality; therefore, population sizes are greater so that species interactions are more likely. High competitive pressure and a stable environment allow natural selection to narrow the niche requirements of the species, allowing the environment and resources for which they are competing to be partitioned to a finer degree than otherwise possible. This would result in more species coexisting per unit area of habitat in the tropics than in temperate areas. This hypothesis assumes that competition is not as important in temperate and higher latitudinal regions, and that in these regions the physical environment plays a greater role in forcing natural selection and evolution. The validity of this assumption remains an open question.

A second hypothesis assumes there are more predators (including herbivores) in the tropics. Predators remove prey biomass, thereby reducing competition among the prey species by reducing the demand on available resources. Under this hypothesis, competition is also less intense in the tropics, not because the species have evolved to avoid it through partitioning the environment more efficiently but because prey biomass is reduced to such an extent that competition is significantly reduced. The assumption that predation is

more important in tropical ecosystems also remains an open question.

Productivity

Productivity is defined as the rate at which biomass is accumulated per unit area. Many hypotheses have attempted to relate the productivity of different ecosystems to diversity; however, they are not always easy to disentangle from one other and from other hypotheses (e.g., the solar energy hypothesis).

One line of reasoning suggests that low-productivity environments (e.g., those at higher latitudes) can support only a limited resource base (e.g., a low-productivity environment might be able to support a herbivore species but at a population density too low to support a predator higher in the food chain). In contrast, in a high-productivity tropical environment a herbivore population might be large enough to support several predatory species. Also, in high-productivity environments food might be more abundant, allowing the opportunity for predators and herbivores to specialize more finely, resulting in a greater number of species (see the discussion in the previous section on the ecological niche).

Another suggestion is that although total productivity over the course of a year might be higher in the tropics than that in other regions, instantaneous rates at other latitudes are much higher (e.g., the flush of plant growth during spring at more temperate latitudes). This effect, combined with low nutrient availability in the tropics, would result in overall lower population growth rates in tropical species, which would tend to slow rates of competitive exclusion and hence extinction. Although slow rates of competitive exclusion cannot explain enhanced diversity on their own, when population sizes are continually impacted upon by external factors such as disturbances, under certain conditions the slow competitive exclusion can be converted into species coexistence, thus promoting higher diversity.

Summary

There are consistent trends in global biodiversity across the various ecosystem types which broadly correlate with latitude. Many hypotheses have been proposed to explain this gradient; however, the spatial and temporal scales over which the processes of speciation and extinction take place make rigorous testing of these hypotheses extremely difficult. As a result, there is still no consensus on which of the hypotheses might be the most important in determining actual gradients. A further difficulty in identifying the primary causes of the latitudinal diversity gradient is that many of the hypotheses are intimately related, with the potential for many of them to be acting in unison to determine the diversity of a particular ecosystem. It is also likely that the relative importance of different hypotheses varies both across different ecosystems and through time.

Because the latitudinal diversity gradient appears to be a universal pattern across a wide range of different kinds of organisms, it is likely that there must be some common explanation. The challenge for the future is to identify which factors, particularly which combinations of factors, are the primary causes of this pattern.

Glossary

Andepts Soils derived from andesitic volcanic ash.

Australasia Geographic region that encompasses Australia, eastern Indonesia, and nearby islands of the tropical southwest Pacific.

Great faunal interchange Development of the Central American isthmus facilitated the interchange of fauna from north to south and vice versa.

Indo-Malaya Geographic region from India to Malaysia and western Indonesia.

Intertropical convergence zone (ITCZ) Low-latitude region characterized by warm air masses and convectional rainfall; also known as the heat or thermal equator.

Neotropics Tropical portion of Western Hemisphere ranging from southern Mexico to northeastern Argentina, including the Caribbean and the tip of Florida; New World Tropics is synonymous.

Paleotropics Tropical regions of the Eastern Hemisphere extending from Africa through south and southeast Asia into the southwest Pacific; also known as Old World Tropics.

Rain shadow Less rainy sector on leeward side of mountains and protected valleys caused by descending warm air masses.

Terra firme Nonflooded landscape in tropical lowlands, usually characterized by highly weathered nutrient-poor soils.

Introduction

Though covering only 9% of the Earth's land, tropical forest ecosystems are famous for their exuberant greenness, impressive structure, and striking diversity of fauna and flora – and how poorly studied they are. Despite their attraction to nineteenth-century explorers such as Charles Darwin, Alexander von Humboldt, and Alfred Russell Wallace and the development of permanent field stations in the twentieth century (McDade *et al.*, 1994), we still know very little about the biodiversity in tropical forests and how species function and interact in these ecosystems. For example, the huge uncertainty about the total number of species on our planet is largely due to how little is known about the invertebrates living in tropical forest ecosystems. Even though the phrase “tropical rain forest” still conjures up vivid images and myths about this signature ecosystem, there is a great amount of variety and heterogeneity in the types and extent of tropical forest ecosystems (Leith and Werger, 1989). This essay first provides an overview of the principal physical factors influencing the distribution and variation in tropical forest ecosystems and then describes the major types and features of tropical forest ecosystems.

Physical Factors

Geography

Tropical forest ecosystems are usually differentiated into neotropical (New World Tropics) and paleotropical (Old World Tropics). In contrast to the Amazon's dominance of the Neotropics, the Paleotropics include two major regions: Africa and Asia (Richards and Phillips, 2005). African tropical forest ecosystems occur primarily in the Congo basin and the higher lands that border the basin. Outliers occur in a narrow coastal band of West Africa and in the Eastern Arc Mountains of East

Africa (White, 1983). A narrow strip of tropical forests occurs along the eastern coast of Madagascar and on the western Ghats of India, as well as in patches on islands of the Indian Ocean. Because of striking biogeographic differences (e.g., Wallace's Line), tropical Asia is further differentiated into the Indo-Malayan and Australasian regions (Whitmore, 1984).

Tropical biogeography is profoundly influenced by the degree of insularity of major landmasses. For example, the lengthy isolation and connection of Australia, New Guinea, and other islands of Australasia facilitated the striking evolution and diversification of marsupials (e.g., tree kangaroos) in the absence of Indo-Malayan carnivores. The tree family Dipterocarpaceae dominates tropical forest ecosystems in the Indo-Malayan region, but this family has far less importance in Australasian tropical forests. Similarly, the long geological isolation of South America led to a distinctive fauna (e.g., anteaters, sloths, and tapirs) but many of these species were wiped out during the Great Faunal Interchange via the Central American isthmus (Bermingham *et al.*, 2005). In contrast, the continued isolation of oceanic islands (e.g., Galápagos and Madagascar) has enabled some of the unique fauna and flora to survive.

The latitudinal extent of tropical forest ecosystems is not defined by the astronomical limits of the tropic of Capricorn (23°30' S) and the tropic of Cancer (23°30' N). The ecological limits are determined by winter cold (which may not mean freezing temperatures) and inadequate rainfall to support forest vegetation. In general, tropical forest ecosystems extend farther poleward where moisture is adequate, such as in the moist lowlands of Australia, Madagascar, and Mexico. Where aridity precludes the presence of lowland forest (e.g., Argentina and India), tropical forest ecosystems may extend to higher latitudes on the flanks of cooler and moister mountains.

Though approximately 85 countries contain tropical forest ecosystems covering 18 million km², equivalent to about double the area of the USA, the top 10 countries comprise

Table 1 Top 10 countries with tropical forests

Rank	Country	Forests (km ²)	Cover (%)	Annual change (%)
1	Brazil	5,195,220	62	−0.42
2	Dem. Rep. Congo	1,541,350	68	−0.20
3	Indonesia	944,320	52	−0.71
4	Sudan	699,490	29	−0.08
5	India	684,340	23	+0.21
6	Perú	679,920	53	−0.22
7	Colombia	604,990	55	−0.17
8	Angola	584,480	47	−0.21

66% of this total (see [Table 1](#)). The Amazon basin, shared by eight countries, has by far the largest area of tropical forest ecosystems, with five of the top 10 countries by extent of their forests. Vast tropical forest ecosystems also occur in the Congo basin and on the mega-islands of the tropical Far East (Borneo, New Guinea, Sumatra, and Sulawesi). Smaller but significant tropical forest ecosystems occur in the Caribbean, Mesoamerica, trans-Andean South America, coastal Brazil, West Africa, East Africa, Madagascar, South Asia, Southeast Asia, southern China, the Philippines, and many tropical Pacific islands.

Physiography

Regional features such as mountains and water bodies play an important role influencing climate, soils, and vegetation in addition to ecosystem functions. Because major mountain chains (above 2500 m elevation) block the normal flow of air masses, they are the most prominent physiographic feature influencing tropical forest ecosystems. The best example is the Andes, running along the western coast of South America. On the eastern (windward) side, copious rains fall usually throughout the year, whereas on the leeward (i.e., rain shadow) side, coastal deserts dominate – especially in Perú and Chile with the oceanic upwelling of the cold Humboldt Current. Many other mountain ranges (e.g., New Guinea, western India, East Africa, and Mesoamerica) have similar windward–leeward effects on climate and vegetation. Although lesser ranges may not create such striking differences, they provide impressive altitudinal gradients in physical features and they may also be biological barriers. Volcanic massifs (e.g., Mount Kilimanjaro), isolated mesas (e.g., tepuís of southern Venezuela), ancient geologic shields (e.g., Guianan and Brazilian), and uplifted limestone platforms (e.g., Yucatán, northern Borneo, Palawan, and Papua New Guinea) all contribute to the physiographic differentiation of tropical forest ecosystems.

Mountainous regions and high rainfall generate impressive river systems such as the Amazon, Brahmaputra, Congo, Ganges, Mekong, Niger, and Orinoco. These complex hydrographic systems both facilitate and impede ecological connections. The Amazon basin has three major types of streams: (1) white water (originating in the Andes and carrying relatively fertile sediments), (2) clear water (originating from terra

firme in the lower basin), and (3) black water (originating from white sand in the basin). Tributaries cut deeply into mountain flanks and carry huge sediment loads. Their natural floodplains are vast, creating unique ecosystems such as the famous flooded forests in the Amazon basin. Major rivers also meander over surprisingly large areas (~25%), reworking the sediments into new landforms and creating oxbow lakes.

Continental islands (Australia), marine islands (e.g., Antilles, Galapagos, Hawaii, Madagascar, and south Pacific), islands on the continental shelf (e.g., Borneo, Hainan, Java, New Guinea, Philippines, Sri Lanka, Sulawesi, and Sumatra), and innumerable smaller islands are important physiographic features. Owing to degree of isolation, proximity to the “mainland,” and colonization/extinction events, islands may develop distinctive fauna and flora that make significant contributions to tropical biodiversity.

Climate

Tropical climates are characterized by predictable temperature patterns with modest seasonal variation and precipitation regimes that are much more unpredictable and highly variable from year to year ([Kellman and Tackaberry, 1997](#)). Daily temperature range (on a sunny day) is far greater than the seasonal variation between the warmest and coolest months. In mountainous terrain, the daily temperature variation may be as large as 20 °C. Seasonal differences are usually determined by rainfall patterns, such that the dry season is called “summer” and the wet season is “winter.” The rainy season(s) tracks the movement of the thermal equator, also known as the intertropical convergence zone (ITCZ), which is approximately 1 month behind the passage of the sun. The ITCZ brings a daily pattern of afternoon convectional rains, often via thunderstorms or the monsoon. When the ITCZ is seasonally away from the region, it is usually the dry season. When the sun is in the Southern Hemisphere, the northeast tradewinds dominate the Northern Hemisphere subtropics, for example, the Caribbean and Africa. In contrast to the persistent tradewinds, the Asian monsoon involves a reversal of winds, with a summer inflow of warm moist air and a winter outflow of cool, dry air.

In the Caribbean, the tradewinds pass over warm seawater, bringing considerable moisture and clouds to mountainous

land near the sea. The cloud cover and moisture create the renowned cloud forests of the windward Caribbean region, such as Monteverde (Costa Rica), Blue Mountains (Jamaica), El Verde (Puerto Rico), and Rancho Grande (Venezuela). On the opposite side of the mountains, descending tradewinds produce much more arid forest ecosystems on the leeward slopes. The same windward–leeward phenomenon occurs on the slopes and valleys of major mountain ranges such as the Andes and Himalayas (Hamilton *et al.*, 1995). The front ranges are exposed to moisture-laden air masses and orographic rainfall, while interior valleys are much more arid.

In tropical regions, considerable between-year variation in total rainfall and its seasonality is the normal pattern, regardless of the average annual rainfall. Long-term rainfall records indicate that the annual maximum is usually more than twice the amount of the driest year. Near the equator, there are usually two alternating rainy and dry seasons, each approximately 3 months in duration. As one moves away from the equator, one dry season (when the sun is in the other hemisphere) lengthens and the other shortens or disappears. Rainfall regimes tend not to be simple or predictable, because short rainless periods can occur during the rainy season or isolated rains can occur during the dry season. The El Niño Southern Oscillation (ENSO) phenomenon occasionally eliminates or greatly delays one of the seasons; that is, the rains may be very late in arriving or they may override a normal dry season.

Soils

Tropical soils have been influenced by major geologic phenomena such as plate tectonics, weathering of ancient landscapes, uplifting of mountain ranges, volcanic outputs, and oceanic submergence or emergence. Erosion of the ancient Guianan shield contributed the extensive white sand soils of the Río Negro basin, leaving the impressive flat-topped mesas (“tepuís”) that dominate southern Venezuela. Many of the infertile, terra firme soils of the Amazon basin were eroded from the geologically ancient Brazilian shield. The active floodplains of several major western Amazonian rivers receive sediments eroded from the geologically young Andes, thus juxtaposing annually renewed, fertile floodplain soils with the infertile terra firme soils that are so typical of much of the Amazon basin.

Much volcanic activity has characterized the Quaternary, especially in mountainous regions of the Tropics. Volcanic ash deposits and mudflows tend to be more prevalent than lava flows (Hawaii is an exception). There are two major types of volcanic ash: andesitic and rhyolitic; the former is rich in certain nutrients, whereas the latter is high in silica. Soils developed from andesitic ash are termed “andepts” and are famous as the best soils for coffee or tea (e.g., Assam, Colombia, Central America, Hawaii, Jamaica, Java, and Kenya). The natural fertility of andepts is the foundation of the highly productive paddy rice cultures of Southeast Asia. In contrast, extensive soils derived from rhyolite in Honduras and Nicaragua have low agricultural potential and are dominated by open pine forests.

Tropical soils vary greatly in their principal chemical and physical properties, such as parent material, soil structure, drainage regime, and age. Variations in soil properties play an

important role in the different types of tropical forest ecosystems; however, we do not know much about their controlling influence on the distribution of most tropical tree species. The more restrictive a site is, the more distinctive the vegetation may be. For example, the combination of nutrient-poor, white sand soils and a perched water table in southern Venezuela gives rise to a dwarf shrubby vegetation (“bana” or “caatinga”) in a tropical rain forest region.

Major Forest Ecosystems

Tropical forest ecosystems are extremely rich in species of both fauna and flora. The highest tree species richness numbers – approximately 300 species per hectare – have been documented from the western Amazon and northern Borneo. Lowland forests of the tropical Far East and Amazonia are far richer in species than is the Congo basin. Even more striking is the fact that if one excludes tree species from the total floristic richness, tropical forest ecosystems are still the richest ecosystems in the world, due to the species diversity of nontrees such as epiphytes and climbers (Gentry, 1990). Given similar rainfall regimes, central Amazonian forests tend to have fewer epiphytes than Mesoamerican forests, whereas tree species richness may be three times greater in the former.

There are many classification systems for differentiating tropical forest ecosystems that use bioclimatic, structural, or floristic criteria (Holdridge *et al.*, 1971). Each has its purposes and merits, but they are too detailed for general overview purposes such as this article. Rather, a simple artificial system (Hartshorn, 2000) is used that first recognizes three elevational zones – lowlands (<500 m), low mountains (500–2000 m), and high mountains (>2000 m) – and then differentiates three major moisture regimes – perhumid (wet), humid (intermediate), and subhumid (seasonally dry). Brief overviews are also included for some distinctive tropical forest ecosystems such as mangroves, flooded forests, savannas, and páramo. The interested reader must keep in mind that these are arbitrary groupings along continuous gradients, analogous to differentiating the colors of the rainbow, and that it is impossible to assign regional altitudinal or rainfall limits for major types of tropical forest ecosystems.

Lowlands (<500 m)

Classic lowland tropical forest ecosystems extend onto the foothills and lower slopes, but it is difficult to define an upper ecological limit for the lowlands. Some authors prefer an elevation (e.g., 1500 m), whereas others use the upper limit of typical lowland crops (such as the “coffee line”) or more conventional bioclimatic, structural, or floristic criteria. To include the very representative lowlands of the Amazon and Congo basins (with base elevation of ~300 m) as well as extensive foothills, the arbitrary upper limit of 500 m for lowlands is used here.

Mangroves

The mangrove forest ecosystems, probably the best known tropical forest ecosystem, are characteristic of most tropical

coastal zones due to the ability of several unrelated tree species to grow in saline conditions. Mangroves are typical of estuaries, deltas, and low-energy coasts lacking strong wave action. Owing to greater tidal fluctuation and lower base flow of rivers associated with longer and more severe dry season, mangrove forests extend substantially farther inland on the western side of landmasses than on eastern coasts. For example, mangroves extend 190 km inland along the Gambia river in West Africa. Neotropical and West African mangrove forests have far fewer tree species than the mangroves of the Indian Ocean and the tropical Far East. Most mangrove species have evolved effective ways of dealing not only with their salty environment (e.g., leaves that exude salt through specialized glands), but also with the anaerobic sediments in which they grow. Mangrove ecosystems are important nurseries for shellfish as well as finfish and offer frontline buffering against tropical storms.

Flooded Forests

In the wet lowlands, flooded forests occur behind the mangroves (where salinity does not influence the floristic composition of the forests), along many major rivers such as the lower Amazon and in low-lying areas with poor drainage. The frequency, depth, and length of flooding appear to be important physical factors determining the composition and dominance of flooded forests. Many flooded forests are pure stands of a single tree species, such as *Campnosperma brevipetiolatum* (New Guinea), *Campnosperma panamensis* (Panama and Costa Rica), *Mauritia flexuosa* (Amazon basin), *Manicaria saccifera* (Neotropics), *Mora oleifera* (circum-Caribbean), *Nypa fruticans* (New Guinea), *Prioria copaifera* (Central America), *Pterocarpus officinalis* (Costa Rica), *Raphia taedigera* (Neotropics and West Africa), and *Shorea albida* (Borneo). We do not have a good understanding of why any one of these species is able to dominate a particular ecosystem.

In contrast to flooded forests dominated by a single species, more heterogeneous flooded forests occur farther from the sea or adjoining the pure stands. The dominant tree species of pure stands also occur in the more mixed forests, usually with far less dominance. Swamp forests may have very large trees, but tree density tends to be lower in swamp forests than in adjoining terra firme forests. Most tree species are not restricted to swamp or flooded forests, but may occur on terra firme, where rainfall is adequate and especially where there is no effective dry season. Even with a mixture of tree species, these flooded forests are not nearly as species rich as nearby terra firme forests.

Many tree species that occur in flooded forests have large seeds that float, as can be seen in the flotsam on tropical beaches. One of the most characteristic trees of tropical beaches, the coconut (*Cocos nucifera*, Palmae), has such a wide pantropical distribution that it is difficult to determine its geographic origin. Several tree genera with large, buoyant seeds have the same or a sibling species across the Atlantic Ocean, such as *Elaeis* (Palmae), *Pentaclethra* (Mimosaceae), *R. taedigera* (Palmae), and *Sacoglottis* (Humiriaceae).

Perhumid Forests

Lowland perhumid forests are well known as classic tropical rain forest (Richards, 1996). Curiously, these forest ecosystems are more typical of the foothills and lower slopes of front

ranges than of the extensive Amazon or Congo lowlands. The absence of major mountain ranges in tropical Africa may be a factor in the comparative scarcity of perhumid forest ecosystems there, especially in the Congo basin. Coastal West Africa from Guinea to Liberia is one of the few regions on that continent with average annual rainfall exceeding 3000 mm. Other lowland perhumid forests (e.g., southeastern Mesoamerica, Colombian Chocó, Gulf Province of Papua New Guinea, north Borneo, and Chittagong in Bangladesh) may have annual rainfall of 6000–10,000 mm.

Lowland perhumid forests on adequately draining soils have high tree diversity, consistently exceeding 100 species per hectare for trees 10 cm or more in diameter (diameter at breast height (dbh)). Some centers of diversity usually exceed 200 tree species per hectare and a few exceptional areas (e.g., eastern Ecuador, northeast Peru, central Guyana, and northern Borneo) report more than 300 tree species per hectare. Though forest stature may be lower and tree density higher on poor soils, these forests typically have 500–600 trees per hectare (>10 cm dbh). Thus, the great majority of tree species are represented by only one individual per hectare. Lowland perhumid forests on terra firme soils with adequate drainage show considerable variation in the distribution of tree species over a mosaic of forest types.

Palms are very rich in species in lowland perhumid forest ecosystems. Because of their distinctive leaf form, palms are conspicuous in these forests, ranging from dwarf species (<1.5 m tall) to understory colonial species, to elegant single stems that reach the subcanopy, and to the famous climbing rattans. A few palm genera have radiated into several hundred species of climbing palms in the Indo-Malayan region; commercial rattan comes from robust climbing palms. In neotropical forests, the climbing palm, *Desmoncus*, has just a few dozen species and they are not nearly as abundant as the rattans of the tropical Far East. In some neotropical forests (e.g., La Selva in Costa Rica), palms comprise up to 25% of the stems (>10 cm dbh) in heterogeneous old-growth forests. Palms tend to be less abundant and less diverse in secondary forests.

Plants dependent on other plants for support, such as epiphytes, climbers, and stranglers, are abundant in lowland perhumid forests, especially on tree branches in the forest canopy. Many plant families have epiphytic species, but most typical of lowland perhumid forests are orchids, ferns, gesneriads, and bromeliads – the latter are restricted to the Neotropics. There are even epiphytic cacti (*Epiphyllum* and *Rhipsalis*) in lowland perhumid forests. The latter genus (with sticky, bird-dispersed seeds) is the only member of this neotropical plant family present in Africa. Lianas (woody climbers) are one of the most striking components of tropical forests because of their growth form, stem structure, and impressive size; they may be 35 cm in diameter and greater than 100 m long as they drape over the crowns of canopy trees. Many plant families are represented by lianas, but they are especially common in the Apocynaceae, Bignoniaceae, Dilleniaceae, Fabaceae, and Marcgraviaceae. In contrast to robust lianas, slender herbaceous climbers are typical of the Araceae, with hundreds of species in several genera.

Although some stranglers belong to the genus *Clusia* (Clusiaceae), most are figs (*Ficus*, Moraceae). A strangler

begins life as an epiphyte, sending down aerial roots, eventually forming an interconnected network of roots that embrace the host tree. A strangler may survive as an independent tree for many years after the host tree dies and decomposes, leaving a “hollow cylinder” as its testimony. Interestingly, the strangling part of this relationship has not been confirmed; death may be associated with the inability of the host tree to tolerate shading by the strangler. Each fig species is pollinated by a unique species of tiny fig wasps, representing one of the best examples of coevolution. Figs are important keystone food resources for vertebrate fruit eaters in many tropical forests.

Lowland perhumid forests are extremely dynamic because tree falls are frequent events. The fall of a large canopy tree creates a sizeable opening in the forest canopy and prime regeneration sites on the forest floor. Up to 50% of the tree species in heterogeneous old-growth neotropical forests may be shade intolerant and dependent on canopy gaps for successful regeneration. In addition to the well-known “fugitive” pioneer species (e.g., *Cecropia*, *Macaranga*, *Musanga*, *Ochroma*, and *Trema*) that characterize the rapid recolonization of disturbed areas, many valuable timber species – such as mahoganies, Spanish cedar, and dipterocarps – require gaps to reach the canopy. Numerous studies of many tropical forests over the past few decades indicate that turnover rates in the order of 100 years are the norm in tropical forests. Gap-phase dynamics appears to be an important ecological contributor to the maintenance of species-rich tropical forests.

Humid Forests

Lowland humid forests are the most widespread of tropical ecosystems, covering much of the Amazon and Congo basins, Mesoamerica, and the tropical Far East. Mean annual rainfall typically exceeds 1500 mm, but the upper limit is more related to the seasonality of rainfall. Although lowland perhumid forests have only a short or ineffective dry season, lowland humid forest ecosystems are characterized by a significant dry season. These latter forests are almost as equally impressive as the former (e.g., the tallest trees in Ghana reach 60 m); however, the number of deciduous trees is much greater in the seasonal forests. Epiphytic orchids and gesneriads are less abundant in the canopy of humid forests than in perhumid forests. Smaller, thin, and supple woody vines are more common in humid forests, perhaps related to the greater proportion of deciduous species in the forest canopy. Large palms are common subcanopy components in humid forest ecosystems. Because of fire tolerance and the adaptive strategy of building the trunk belowground, some of these palms (e.g., *Attalea speciosa*, *Copernicia* spp., and *Scheelea rostrata*) are aggressive colonizers of pastures created from humid forests and maintained by fire.

Seasonal rains and drought not only determine the ecological functions and processes, but also have strong influence on the populations of animals and plants (Leigh *et al.*, 1982). The synchronization of flowering with the dry season is truly impressive. Flowering during the dry season when tree crowns and lianas are deciduous facilitates visitation by pollinators such as large bees. The alternation of rainy and dry seasons and the use of seasonal changes to trigger physiological responses (i.e., flowering, insect emergence, nesting, and rearing

of young) make these ecosystems unusually susceptible to climatic fluctuations such as ENSO events. The best example is the ENSO-caused rains during the dry season that occasionally limit flowering and cause famine among fruit-eating animals on Panama's Barro Colorado Island (BCI).

The pioneering studies of the spatial distribution of trees by Hubbell and associates on BCI indicate that very few tree species are hyperdispersed as suggested in the classic literature on tropical forests. Many species have the adults randomly distributed, while some species show clumping. For example, several caesalpinoid legumes (*Brachystegia laurentii*, *Cynometra alexandri*, *Gilbertiodendron deweyi*, and *Julbernardia seretii*) form single-species stands in the Congo basin. A long-term study on the 50-ha plot at BCI has elucidated evidence for strong density dependence within species, suggesting an important role for interactions between plants and their predators and pathogens. The spatial distribution of plants has important consequences on pollination, breeding systems, herbivory, and successful regeneration.

One of the most famous tropical trees is the Brazil nut (*Bertholletia excelsa*, Lecythidaceae), which has a patchy distribution in Amazonian humid lowland forests. Because adult trees occur in clumps, there has been considerable conjecture about indigenous influence on the abundance of this valuable species. Detailed studies document that the clumping is natural, probably due to the scatter-hoarding behavior of forest agoutis (*Dasyprocta leporina*, Heteromyidae) that cache seeds for later use. Another neotropical tree species with an unusual distribution is the true mahogany (*Swietenia macrophylla*, Meliaceae), which is reasonably abundant in the subtropical humid forests of northern Mesoamerica and the southern Amazon basin but quite scarce in the intervening tropical forests. Because of its high-value timber, there have been numerous attempts to promote or increase its abundance in natural forests, but they have mostly failed. Recently, it has been suggested that mahogany requires large-scale disturbance such as by fire or river meanders, creating the high light regime needed for establishment and growth of young trees.

One of the more fascinating historical aspects of this ecosystem is the development of truly impressive human civilizations such as the Maya in northern Mesoamerica and the Khmer in Kampuchea (Cambodia). Both cultures developed intensive agriculture based on sophisticated engineering and management of water during the dry season through the use of raised fields, irrigation canals, and paddies. The Maya are believed to have also favored particularly useful plants such as mahogany, *Manilkara zapota* (Sapotaceae), and *Brosimum ali-castrum* (Moraceae). Approximately 900 CE, the classic Maya civilization collapsed, perhaps due to overpopulation and/or a prolonged, severe drought. Given our current understanding of tropical forest dynamics, it is quite unlikely that the humid lowland forests now occupying the classic Maya region are successional forests.

Subhumid Forests

Lowland subhumid tropical forest ecosystems are much more extensive in the Paleotropics (e.g., Madagascar, India, and Indochina) than in the Neotropics. The high-value teak (*Tectona grandis*, Verbenaceae) forests of Burma, Thailand, and Java are representatives of this ecosystem, as are the vast sal forests

(*Shorea robusta*, Dipterocarpaceae) of northern South Asia. These ecosystems also occupy significant areas in the Caribbean, along the Pacific coast of Mesoamerica (Bullock *et al.*, 1995) and northeast Brazil. Mean annual rainfall seldom exceeds 1500 mm, but the determining ecological factor is the long and severe dry season. Because of the historic pastoralist tradition in this ecosystem and the prevalence of nearly annual fires, most lowland subhumid forests have been destroyed or severely degraded by centuries of use (Laurance and Peres, 2006). One of the most notable exceptions is the well-studied dry forest of Guánica on the south coast of Puerto Rico (Lugo and Lowe, 1995). This island is unusual in that the economic pressures to use land were not nearly as intense in the twentieth century compared to most developing countries.

Lowland subhumid forest ecosystems have far lower tree species richness than humid and perhumid forests. They are also much shorter in height and simpler in structure, but virtually all woody species are deciduous. In low-stature forests, the shrub layer is often dense and very spiny; thin lianas are abundant (including the *Vanilla* orchid), but epiphytes are less rich in species and abundance. Terrestrial cacti and bromeliads are more common, especially on extreme sites such as rock outcrops. At the latitudinal limits of the Tropics, lowland subhumid forest ecosystems include chaparral, open pine forests, and mixed oak–pine forests – depending primarily on moisture availability. Evergreen forests occur in riparian situations and in other moist sites such as in karst (limestone) terrain, where underground moisture is available during the long dry season.

In contrast to the pure stands in some freshwater swamps mentioned earlier, pure stands in lowland subhumid forest ecosystems usually can be attributed to edaphic factors, such as rhyolitic ash (tuff or pumice) or montmorillonite clay (black cotton soils). One of the more distinctive forests is the pure stands of the only lowland tropical oak species, *Quercus oleoides*, that has a patchy distribution on rhyolitic ash deposits from southern Mexico to northwestern Costa Rica. Appreciable areas of lowland subhumid forest ecosystems in Mesoamerica exhibit single-species dominance, such as *Celaenodendron mexicanum* (Euphorbiaceae), *Crescentia alata* (Bignoniaceae), *Erythrina fusca* (Fabaceae), and *Parkinsonia aculeata* (Caesalpinaceae). Despite the attribution of these single-dominant stands to restrictive soil factors, there is precious little clarity as to why a species is able to attain such dominance.

Savannas

Savannas are defined as having a continuous cover of grass, but trees may be conspicuous components of savanna landscapes. Though vast areas in the major tropical regions meet the criteria for savannas, it is much more difficult to ascertain if it is natural or derived through human activities (e.g., burning). Tropical Africa epitomizes the image and grandeur of savannas with vast expanses of grass, sparse trees, migratory herds of herbivores, and their predators. Recently, the role of elephant herds in transforming woodland to savanna has been well documented. Extensive savannas also occur in the tropical Far East and the Neotropics (the llanos of Colombia and Venezuela, Rupununi in Guyana, and Beni in Bolivia).

The extensive pastures of Mesoamerica are considered to be derived savannas created by almost annual burning to “freshen” pastures and suppress woody invaders. Neotropical savannas have some very characteristic and fire-resistant tree species, such as *Acrocomia vinifera* (Palmae), *Byrsonima crassifolia* (Malpighiaceae), and *Curatella americana* (Dilleniaceae). Lowland pine (*Pinus caribaea* var. *hondurensis*, Pinaceae) savannas occur in northeastern Nicaragua, much of lowland Honduras, part of the Guatemalan Petén, and east central Belize. In contrast to the derived savannas of Mesoamerica, the pine savannas appear to be natural ecosystems maintained by frequent fire. The flat pine savannas of Belize occur on sandy soils that flood during the rainy season and undergo severe drought in the dry season.

Low Mountains

For purposes of this essay, low-mountain ecosystems occur between 500- and 2000-m elevation. The rather arbitrary upper limit represents the maximum extent of tropical lowland flora near the equator. In many regions, the transition to montane flora more typically occurs by 1500 m, while nearer the latitudinal limits of the Tropics, this transition can be as low as 500 m. This elevational limit for tropical plants is more noticeable with crops such as highland coffee (*Coffea arabica*, Rubiaceae) or tea (*Camellia sinensis*, Theaceae). Low-mountain ecosystems typically have a mixture of tropical and temperate fauna and flora; for example, pines and oaks are conspicuous trees in northern Mesoamerican forests. Some tree genera have pairs of closely related species, with one occurring at lower elevations and the other in higher elevations in Mesoamerica, for example, *Billia* (Hippocastanaceae), *Brunellia* (Brunelliaceae), *Hedyosmum* (Chloranthaceae), and *Symplocos* (Symplocaceae). In some ways, low-mountain ecosystems between 500 and 2000 m are transitional between lowland tropical and tropical montane floras. These ecosystems are typical of the major mountain ranges as well as the many smaller chains and high plateaus (e.g., Brazilian Shield, Serengeti Plain, and Great African Plateau).

Subhumid Forests

Low-mountain subhumid forest ecosystems are common on leeward slopes and in valleys and plateaus protected from orographic rain. Because of favorable climate, this ecosystem has had a long history of human activities, leaving little natural vegetation. Subhumid forests are relatively open and low in stature, with an abundance of spiny trees and shrubs, especially Mimosaceae. In northern Mesoamerica and continental Asia, conifers (*Pinus* spp.) are common in subhumid forest ecosystems. *Pinus kesiya* and *Pinus merkusii* occur in the Malay archipelago, while *Pinus wallichiana* and *Pinus roxburghii* are common on the lower flanks of the Himalayas.

This ecosystem is extensive on the plateaus that border both the Amazon and Congo basins. The Great African Plateau is dominated by miombo woodland (dominated by *Brachystegia*, *Julbernardia*, and *Isoberlinia*, Caesalpinaceae), while the Brazilian shield is characterized by similar open forest (“cerrado”). The Brazilian cerrado are low open forests or woodlands with characteristically crooked trees that occur on

soils high in aluminum and low in pH. Cerrado vegetation exhibits considerable variation, ranging from grass-dominated savanna to fairly dense forest; however, most of the plant species are of tropical origin. Where soils are less restrictive, more typical tropical forest exists that is surprisingly tall (to 40 m), fairly open canopy, with a high proportion of deciduous species.

Humid Forests

Humid forest ecosystems often ring lower, more arid regions on low mountains, because of more moisture and cooler temperatures, and/or less severe drought. Low-mountain humid forests show enormous variation of forest type, structure, and floristic composition due to their widespread distribution and great heterogeneity of physiography, soils, and rainfall patterns. An excellent example of this variation occurs in northern Mesoamerica, where pine forests dominate the upper slopes and broad-leaved forests occur in the valleys. Pines are characteristic of low-fertility soils and frequently burnt sites, with *Pinus oocarpa* often dominant. The broad-leaved forests usually have a mixture of tropical (e.g., *Alchornea*, Euphorbiaceae) and temperate tree genera. *Parinari excelsa* (Chrysobalanaceae) has an unusually broad distribution in Africa, dominating humid forests in both the Congo lowlands and the Guinea highlands.

Impressive tropical forests occur on fertile soils (i.e., andepts) in Mesoamerica, with a high density of canopy trees (typically in the Lauraceae and Sapotaceae) plus occasional tall (> 50 m), emergent trees of *Ulmus mexicana* (Ulmaceae). Also occurring in these mid-elevation humid forests are canopy trees of Podocarpaceae (Southern Hemisphere conifers), Juglandaceae, and Proteaceae. The latter tree family (that includes *Macadamia*) is especially diverse and abundant in the Queensland Wet Tropics of northeastern Australia.

Perhumid Forests

These high-rainfall ecosystems are common on the flanks of low mountains and ranges that receive moisture-laden clouds from the east. When the mountains are oriented more or less perpendicular to the prevailing air currents, they nurture the famous cloud forests of the Caribbean, Mesoamerica, northern and eastern Andes ("ceja de selva" and "yungas"), and even on isolated volcanic massifs. Perhumid forests on low mountains may have tree species richness comparable to lowland perhumid forests. They also exhibit complex vertical structure and fairly tall trees; the latter may be related to the better drainage and anchorage typical of dissected topography.

Canopy trees are usually evergreen (with abundant epiphylls) and with heavy epiphyte loads, including bryophytes, shrubs, and even small trees. The abundant mosses in the canopy give these perhumid forests a distinctive brownish hue visible from small planes. Epiphytic Ericaceae shrubs are usually very abundant in cloud forests, providing year-round nutrition to nectar-feeding birds. The sizeable and heavy (when wet) loads of organic material in tree crowns cause frequent branch falls as well as stimulating the host tree to produce feeding roots on the branches to take up nutrients. In perhumid forests on nutrient-poor soils, numerous species of insect-trapping, epiphytic pitcher plants (*Utricularia*, Lentibulariaceae) are quite abundant.

High Mountains (> 2000 m)

Because several tropical lowland species and crops may grow on protected sites up to 2000-m elevation, we use this as the lower limit of high-mountain forest ecosystems. High mountains in the Tropics have a temperate climate characterized by warm diurnal temperatures (on a sunny day) and cold nocturnal temperatures, including occasional freezes. In Africa, the fairly isolated mountains are defined as the Afromontane zone. Treeline varies considerably between approximately 3300 and 3800 m, depending on moisture, disturbance by fire, and proximity to the equator. Despite the temperate climate, most forest ecosystems have distinctive tropical features such as epiphytes and lianas. Nevertheless, the high-mountain tropical flora has much stronger affinities with temperate zone flora (Churchill *et al.*, 1995).

Subhumid Forests

In the Afromontane region of East Africa, *Juniperus procera* (Cupressaceae) forms pure stands; however, it is unclear if human disturbance is a contributing factor to this species' success. It is possible that high-mountain subhumid forests once existed on the Andean Altiplano, but centuries of human activities have destroyed most natural vegetation. The only remnants may be the small stands of *Polylepis* (Rosaceae) that occur up to 4000-m elevation in the central Andes – the highest forests in the world. The forest patches persist on rocky slopes that may provide natural protection from frequent fires, and soil temperatures may be slightly higher. *Polylepis* trees are small, twisted, and gnarled, with considerable trunk and branch dieback, especially on stand edges.

Humid and Perhumid Forests

The high elevations and cool temperatures tend to produce a preponderance of humid and perhumid forest ecosystems because of frequent cloud cover and low evapotranspiration. These ecosystems usually have the canopy dominated by holarctic genera (e.g., *Pinus*, *Quercus*, and Lauraceae), whereas the understory is more of a mixture of holarctic and tropical genera. Northern Mesoamerican forests are the center of diversity for oaks (*Quercus*, Fagaceae) and conifers (*Abies*, *Cupressus*, *Juniperus*, *Pinus*, *Podocarpus*, *Taxodium*, and *Taxus*). Except for *Podocarpus*, these are all holarctic genera. On poor soils, the coniferous forests tend to be open and frequently degraded by grazing and fire. More fertile and/or wetter sites also have conifers, but the forests are more of a mixture with oaks. Northern Hemisphere conifers do not occur naturally south of the Nicaraguan lowlands; thus oaks dominate the high-mountain forests of southern Mesoamerica and Colombia. The bamboos *Chusquea* in the Neotropics and *Arundinaria alpina* (both Poaceae) in East Africa are typically very abundant in the understory, where they may be impeding natural regeneration of trees. As with lower elevation perhumid forests, the large canopy trees carry huge epiphyte loads of mosses, tank bromeliads, and ericaceous shrubs.

Páramo

Although not strictly a forest ecosystem, high-mountain páramo merits brief mention as a unique high-mountain tropical ecosystem. Subalpine páramo occurs above treeline on high

mountains in the Neotropics (Ecuador to Costa Rica) and East African volcanic massifs. Neotropical páramo is characterized by a high density of shrubs, including *Chusquea*, *Hypericum* (Hypericaceae) and *Vaccinium* (Ericaceae), and occasional emergent trees of *Clusia* (Clusiaceae). Where drainage is poor, bogs and a distinctive flora are frequent. But the most striking feature in Andean páramo is the abundant postlike *Espeletia* (Compositae) that have a single thick stem topped by a rosette of furry leaves. Afroalpine páramo has giant *Lobelia* (Lobeliaceae) and giant *Senecio* (Compositae) that are very similar in growth form to *Espeletia*. The thick trunk is fire-resistant and the rosette of leaves may offer some protection from nightly freezing temperatures.

Glossary

Bottom up Those impacts or controls on urban biodiversity that originate from human actions at smaller scales, such as household or neighborhood scales. Tends to increase heterogeneity (diversity) of outcomes.

Ecosystem services The benefits people obtain from ecosystems, including provisioning services, regulating services, cultural services, and supporting services.

Ecotone A transition zone between two or more different ecosystem types.

Hinterland A region lying beyond an urban area, but often influenced by it.

Human ecology A type of ecology focused on a specific species, *Homo sapiens*. Human ecology may be thought of as a subset of social ecology, which is a life science focusing on the ecological study of various social species such as ants, bees, wolves, dolphins, or orangutans.

Social differentiation A term taken from biology to describe the specialization of functions in a society and to

characterize societies over time. Theories of social change propose that increased social differentiation emerges as societies increase in size and complexity. Differentiation is frequently accompanied by a need for increased coordination and increased interdependence in larger and more complex societies.

Synanthropic species Species that live near humans, and benefit from the types of habitats humans create.

Top down Those impacts or controls on urban biodiversity that originate from human actions at larger scales, such as the level of a city or above. Tends to homogenize outcomes.

Urban ecology The study of urban systems from an ecological perspective; an emerging field within ecology that strives to understand human interactions in ecological systems in and around urban areas and to develop theories and analyses that include human communities as fundamental components of ecological systems.

Introduction

In 2010, for the first time ever, more humans lived in urban environments than rural ones. From the advent of agriculture 10,000 years ago, when humans first began gathering in ever-larger settlements, we have transformed ourselves from *Homo Rusticus* to *Homo Urbanus*.

Over this time, we have transformed our cities as well. The largest city in 3100 BCE was Memphis, Egypt, with 30,000 people. At the advent of the Common Era, Rome had nearly half a million inhabitants. The first city to reach a million was Baghdad, Iraq, toward the end of the first century (Chandler, 1987). Today, there are 21 megacities – metropolitan areas with upward of ten million inhabitants.

The ecosystems people create in cities – either intentionally or unintentionally – are unique in Earth's history. Plants from many major global biogeographic regions – having no coevolutionary history – can be found within a few yards of each other. Cities contain previously wild animal species that have become domesticated, and domesticated animals that have become “naturalized” and free-ranging members of the urban fauna. Cities also exclude certain organisms that cannot tolerate the urban environment, such as the high fragmentation or low area of suitable habitat found there. Species moving through cities – such as birds, insects, reptiles, or small rodents – encounter new biotic communities, new patterns of fragmentation, and fundamentally different resource availabilities.

There are two major reasons scientists study these unique assemblages. The first is precisely because this is the environment most people now experience. Their interactions with “nature” – and their experience of the tangible and intangible goods and services this nature can offer – will be profoundly influenced by the biodiversity found in cities. Second, these unique assemblages give scientists an opportunity to test, accept, or modify ecological theories developed in more “pristine” environments (Collins *et al.*, 2000). Since the vast majority of the world's ecosystems are now human-impacted, if not human-dominated, it is worth understanding how human interactions with the environment structures biological communities and ecological outcomes.

The Founding of Cities and Affected Biomes

Humans, through their creation of urban and near-urban environments, can profoundly affect the distribution and abundance of populations, species, communities, and ecosystems. They do so in many ways, through fragmentation, the mobilization of formerly recalcitrant or scarce resources, preferential cultivation, or destruction. These on-site or near-site disturbances are discussed more systematically later in the text. But before turning to that discussion, it is worth noting that not all biomes are equally susceptible to the disruptions caused by urban settlements. There are certain characteristics that make sites more or less desirable for dense human

settlements. These characteristics have changed over time as our technologies and societies have advanced, allowing acquisition of resources from afar or the defense of even physically vulnerable locations. Nonetheless, we are more apt to find cities nestled in valleys than perched on mountaintops; more likely to find ancient cities on fertile rather than barren soils; more likely to find cities situated on ecotones or “transition zones” – for instance, between the piedmont and coastal plain – because those locations allow access to more diverse resources.

Consider the appearance of the very first urban centers. They would have begun, in many cases, as villages – and later fortresses – around which agricultural fields were established. There would have to be a favorable climate, soil, and a ready supply of water. The labor required for clearing would have to be minimal. There would also have to be locally available productive grains and legumes that were a part of the first “packages” of cultivatable materials. Frequently (but not always), the emergence of agriculture as a dominant means of food procurement over hunting and gathering was aided by the availability of domesticable animals, to be used both as draft animals and as protein supplements. It is only in sites sharing these characteristics that enough food could have been produced to allow population densities to become high enough to form settlements somewhat larger than villages, on their way to being urban centers. We know, in fact, many of the places where agriculture first arose – in Southwest Asia by 8000 BC; Greece, Cyprus, and the Indian subcontinent by 6500 BC; Egypt by 6000 BC; Spain by 5200 BC; and Britain by 3500 BC. The thick forests of the wet tropical regions and the unfavorable climate of the boreal regions made these areas less favorable for the early emergence of intensive agriculture, and thus these biomes were not initially impacted by urban centers.

Later, as civilizations advanced, the need for local agricultural self-sufficiency may have been offset to some extent by the emergence of trade routes. Some urban centers would have been established in areas of particularly favorable mineral or gemstone deposits. Similarly, circumstances of chance or talent would have allowed the emergence of an artisan class within an urban center; both types of sites would have served to anchor the locations of trade routes. Other urban centers may have emerged merely because they were particularly favorable stopping-off places – just a day’s journey up or down the road from a final destination – or because they were at the crossroads of two routes. Nonetheless, there would have been certain characteristics of these sites as well that meant some biomes were more susceptible to disruption from urban centers than were other biomes – those along waterways, coastways, or valley bottoms, for instance.

In current times, technology has allowed the establishment of urban centers in new locations and biomes. Near-global transportation of food products, improvements in our ability to clear land, and our ability to control indoor climate have extended urban centers into deserts, wet tropical forests, and boreal regions. Nonetheless, many of the large urban centers remain in areas of the highest terrestrial productivity. A high percentage of cities continue to be located along waterways or coasts. Much of the growth in urban centers in the coming century will come in those countries with the fastest growing populations; these countries are largely located in the

subtropical or tropical regions of both the Northern and the Southern Hemispheres. Thus, when one thinks about the types of biomes – and thus the types of flora and fauna – likely to be most significantly impacted by urban centers, one should concentrate on temperate forests and grasslands, coastal and riparian zones, savanna/woodland systems, and wet and dry tropical forests. Boreal forests and montane or alpine ecosystems are less likely to be impacted. Desert and arid systems will become increasingly vulnerable as populations grow in the northern regions of sub-Saharan Africa and the North American Southwest, among other locations.

In addition to significant spatial differentiation in the distribution of cities and consequent impacted biomes, there is temporal differentiation as well. Technology not only allows the founding of urban centers in previously unsettled areas but also changes the interactions of a city with its surroundings and the geographic region over which resources are acquired or wastes dispersed. Advances in transportation allow housing expansion in areas farther removed from industrial or commercial centers; advances in architecture allow vertical rather than horizontal expansion of the city center.

Finally, the situation with respect to regional and global levels of development and trade can also profoundly influence the growth and structure of cities. Older cities can display the residual characteristics of their structures of a century ago – residential areas close to the city center, the robust industrial base, or skeleton of that industrial base – that fueled its urban growth. Newer cities, or newer sections of cities, can reflect the dramatic increase in commercial activity fueled by increasingly global and service-oriented industries and the desire for larger homes and more land that comes with economic development.

A Framework for Evaluating Biodiversity in Cities

In the past two decades, scientists have begun augmenting their study of biodiversity with analyses centered on ecosystem services – the tangible and intangible benefits people receive from ecosystems. Human interactions with the environment are often motivated by a need to secure or increase ecosystem services – for example, the food ecosystems provide, or the protection ecosystems might offer from floods or fire. Thus, understanding the ecological patterns people create means understanding the services and benefits they seek to secure.

The recently conducted Millennium Ecosystem Assessment (MA) divided ecosystem services into four categories (MA, 2005). These are:

- *Provisioning services*, which are the tangible products that humans consume, including food, fiber, fuel, and water.
- *Regulating services*, which includes the capacity of ecosystems to prevent or minimize damage from, for example, floods, fires, disease outbreaks, or climate change.
- *Cultural services*, which includes both tangible and intangible benefits provided by ecosystems, such as recreational opportunities, sense of place, or spiritual or cultural well-being.
- *Supporting services*, which are the basic ecosystem processes – such as nutrient cycling or soil formation – needed to deliver all other services.

Many ecosystem services – such as climate regulation through large-scale carbon sequestration – will primarily take place away from cities, in the world's forests and grasslands capable of storing significant carbon. But other services – such as disease regulation, natural-hazard regulation, freshwater provisioning, air-quality regulation, and recreation – need to be produced in or near cities in order to benefit urban residents. If we are to understand how changes in biodiversity alter ecosystem services, we need to understand these relationships in the ecosystems people are creating and experiencing.

Because this is an encyclopedia of biodiversity, the focus here is primarily on the ways in which people are manipulating biodiversity to achieve a set of desired services. People manipulate the biodiversity in cities to achieve certain services, and they do so both “directly” and “indirectly.” That is, some species or taxa are the subjects of deliberate (direct) attempts to secure an environmental good (e.g., a pleasing yard) or avoid an environmental bad (e.g., crown fires near a home). These deliberate manipulations always have “spillover” effects, however, impacting species other than those targeted. Simple examples would include the influences of watering, weeding, and fertilizing practices on soil fauna; or the impact of domesticated animals on bird and small rodent populations (see [Tables 1–3](#)).

People also make decisions that impact urban biodiversity and ecosystem services at various scales – from homeowner to neighborhood association to city manager to multinational organizations governing trade. At each scale, people are pursuing different goals, have different tools available to them to achieve those goals, and operate under different constraints. In the four sections that follow, we examine these goals, tools, and constraints at four different scales – household (individual), neighborhood, cities and their hinterlands, and networks of cities. We refer to those decisions and impacts occurring at smaller scales (household and neighborhood) to be “bottom-up” processes – outcomes at larger scales are the integrated (and often uncontrolled) impact of decisions and actions taken at smaller scales. Because of variations in preferences, values, and economic capacities, bottom-up processes tend to create heterogeneity in the urban landscape, as individual residents or neighborhoods pursue different goals and outcomes. Larger-scale decisions often exert “top-down” pressures on outcomes, either again through deliberate manipulations (e.g., exclusion of certain plants in cities for safety or health reasons) or unintended outcomes (e.g., invasive species that might accompany trade goods). Top-down processes tend to have a homogenizing influence, with many policies or actions having a similar impact across a city or collection of cities. After examining key issues at each scale, we return to the question of how (or indeed whether) our understanding of urban ecology challenges traditional ecological theory.

Individual and Household Scales

Residential properties compose at least a quarter of land in many cities ([Gaston et al., 2005](#); [Mathieu et al., 2007](#)), which means that household-level decisions can have significant impacts on urban biodiversity patterns. Within the outdoor space surrounding homes, residents directly and indirectly affect

biodiversity through yard management and “bottom-up” control of species composition, habitat, resource flows, or disturbances. Household management decisions often reflect residents' personal preferences, such as for easy to maintain or esthetically appealing landscapes ([Larson et al., 2010](#)). However, landscaping decisions are also constrained by residents' capacities (e.g., financial capital, time constraints, and social status) to choose their ideal preferences ([Templeton et al., 1999](#)); social pressures to maintain certain yard types; neighborhood or municipal regulations (e.g., planting restrictions); or the decisions of past land owners ([Boone et al., 2010](#); [Cook et al., 2011](#)). Residents most consciously manage their yard for cultural services (e.g., esthetics and sense of place), provisioning services (e.g., vegetable or flower gardens); and regulating services (e.g., pest, pathogen, climate, or fire control). Other services, such as nutrient cycling, are less often direct goals of management decisions of urban residents, but instead are indirectly impacted by other activities.

At the scale of households, individuals' management practices alter species composition, such that urban vegetation and fauna often differ from the surrounding native ecosystem ([Hope et al., 2006](#)). In particular, people purposefully introduce, care for, and manage certain “desirable” plants in their yards, directly affecting vegetation biodiversity ([Martin et al., 2003](#); [Smith et al., 2006](#); [Loram et al., 2008](#)). In other cases, people remove “undesirable” plants through weeding or the application of herbicides. In addition, fertilizer and watering affect nutrient cycling, increase plant primary production, and support vegetation outside of its typical growing season or range. With available financial and social capital, residents can choose specific landscaping or gardens, for example, to meet their esthetic preferences or attract or deter particular species, such as hummingbirds and scorpions, respectively. As such, urban vegetation diversity and cover are positively related to residents' socioeconomic status ([Hope et al., 2003](#); [Grove et al., 2006](#)).

Residents' intentional manipulation of yard vegetation leads to many direct and indirect impacts on faunal biodiversity ranging from soil organisms to mammals (see [Tables 1–3](#)). The abundance and diversity of fauna that can be maintained within a managed area or yard is directly related to the available habitat, yard type, vegetation density, and distribution. Faunal composition, particularly ground arthropods, can also be directly managed with application of pesticides. Residents choose and maintain groundcover (e.g., grass) and other plant species that in turn influence faunal habitat characteristics, such as microclimate and associated resources. Yard size and pervious area represent the available living space for many organisms and impact the distribution of many urban faunal species. For example, yard area is positively related to bird, butterfly, and small mammal abundance and diversity ([Baker and Harris, 2007](#); [Evans et al., 2009](#)).

Finally, humans directly impact the availability and distribution of resources, such as food and water, which in turn regulate urban plant and faunal populations and their interactions. In residential yards, seasonal variation of resources is often decreased relative to the preurban ecosystems, whereas resource abundance is often also increased ([Shochat et al., 2006](#)). For example, bird feeders and nesting boxes create resources for bird species that would not otherwise remain

Table 1 Human activities that directly target biodiversity in cities, and some of the unintended impacts of such activities. Check marks indicate the *main* taxa impacted by particular activities, but impacts are not limited to these taxa. (Symbols broadly represent common groups of vegetation and fauna: e.g., : **vegetation**; : **birds**; : **mammals (domesticated and wild)**; : **insects and arthropods**; : **reptiles**; : **microorganisms**)

Human action	Targeted taxa	Intentional and unintentional impacts	Other impacted taxa					
								
<i>Household level</i>								
Pets	 	Pets alter the diversity of birds and mammals in the city. Escaped pets can naturalize and become part of the urban fauna. Cats can predate on birds, reptiles, insects, and rodents.		✓	✓	✓	✓	
Bird feeding		People actively feed birds, or plant vegetation that will attract birds. This has implications for the insects, small mammals, and rodents birds may prey on.			✓	✓	✓	
<i>Household, neighborhood, and city level</i>								
Landscaping		Humans create preferred landscapes. This can create broader habitats in neighborhoods with shared sociocultural preferences for certain landscapes. The homogeneity or heterogeneity of these neighborhood habitats will influence birds, insects, reptiles, and small mammals moving through the urban setting. Soil properties and microbial communities are influenced by the chosen plant communities.		✓	✓	✓	✓	✓
Watering & fertilizing		Watering to promote plant growth can attract birds, insects, and small mammals to the city from the hinterlands, particularly in places where water is scarce. Watering and fertilizing affect soil nutrient properties and soil microbial communities.		✓	✓	✓	✓	✓
Pest control	 	People control the prevalence of harmful or annoying insects and rodents, which can have impacts on beneficial insects and rodents, with consequences for plants. Pesticides can alter soil properties and soil microbial communities.	✓					✓
<i>Neighborhood or city level</i>								
Planting restrictions		Neighborhood associations may restrict landscaping choices, and city governments can ban invasive or allergenic plants. This influences the habitat experienced by all other organisms.		✓	✓	✓	✓	✓

Table 2 Some of the decisions and activities of city governments directed toward urban design and infrastructure (e.g., biodiversity is not the target) with significant consequences for biodiversity (symbols same as **Table 1**)

Human action	Intentional and unintentional impacts	Primary affected taxa
Zoning	Zoning restricts land use, and the vegetation associated with that land use (e.g., manufacturing vs. residential).	
Construction	Compacts or removes soils, altering soil microbial communities.	
Roads	Can create conduits for movement of plants, mammals, and reptiles. Roadside deposits from car exhaust can alter soil microbial communities.	
Flood control & groundwater recharge	Cities create retention basins, canals, and levees to redistribute and control water. This affects birds, insects, small mammals, and reptiles that will converge on water sources. The altered soil properties of retention basins will affect soil microbial communities.	

Table 3 A classification of human impacts that affect biodiversity in urban settings

Alteration of habitat
Destruction of habitat
Creation of habitat
Fragmentation of habitat
Alteration of resource flows
Reduction in net primary production
Increase in regional temperature
Mobilization and concentration of nutrients
Dispersion of toxins
Diversion of water and changes in timing of availability
Degradation of water quality
Alteration of disturbance regimes
Increase in small-scale disturbance
Attempts to decrease large-scale disturbance
Unintentional shifts in disturbance
Alteration of species composition
Preferential cultivation or destruction of native species
Introduction of nonnative species

year round (Gaston *et al.*, 2005; Fuller *et al.*, 2008; Davies *et al.*, 2009). Similarly, watering practices directly provide a needed resource for many urban fauna, and water and fertilizer together, through their impact on plant communities, can alter habitat availability. Those species that can thrive on the new, urban patterns of resource availability are called synanthropic species (literally “with humans”). Predator populations are also impacted through both exclusion (e.g., wild cats and some raptors that are ill-suited to urban environments) and introductions (e.g., domesticated pets). When both faunal resources and faunal predators are changed, there can be significant impacts on trophic dynamics (Faeth *et al.*, 2005; Shochat *et al.*, 2006, 2010). Other disturbances to biotic populations include pruning and trimming of vegetation, which can alter patterns and timing of pollination and seed dispersal, as well as natural pest regulation within cities.

Neighborhood Scale

Biodiversity at the neighborhood scale is often an “emergent property” dependent on the personal characteristics and yard

management decisions of many individual urban residents. Ordinances enacted by neighborhood associations or historic preservation societies, however, constrain the landscaping practices of urban residents, and thus have resulting implications for neighborhood biodiversity and ecosystem services. Neighborhood regulations vary by social and biophysical context, but generally focus on collectively maintaining property values and neighborhood cohesion. Still, neighborhood “bottom-up” controls affect urban biodiversity through direct and indirect management for ecosystem services, as well as altered species composition, habitat, resources, and disturbances. Neighborhood ordinances focus on managing for services similar to those at the individual-household scale, including esthetics and a place for recreation (cultural services); and pest, microclimate, flood, and fire control (regulating services). In addition, neighborhood associations may implement measures – such as restrictions on water use (e.g., for flood control) or on certain plant species – to minimize environmental bads; yet, these restrictions can also affect biodiversity.

Neighborhood ordinances frequently regulate plant composition and thus impact habitats and resources for fauna. Specifically, regulations often focus on landscape plantings (e.g., the amount and type of grass and woody plants) in order to visually maintain a cohesive community. For example, in Phoenix, Arizona, neighborhoods with homeowner associations have planting regulations that result in yards with fewer trees, more shrubs, and less turfgrass than neighborhoods without homeowner associations (Martin *et al.*, 2003). Planting regulations in turn impact microclimates and species habitats, and indirectly influence the amount and timing of fertilizer, pesticides, and water applied to a given landscape. The existence of these neighborhood-level regulations, along with the propensity of people to move to neighborhoods where other residents share their landscaping preferences, may mean that the neighborhood scale is of particular relevance in understanding the urban matrix of habitats and corridors that affect urban species (Goddard *et al.*, 2010).

At the neighborhood scale, biotic diversity is also impacted by structural characteristics of the neighborhoods and the households comprising that neighborhood. For example, vegetation diversity and cover are inversely related to housing density and neighborhood age (Marco *et al.*, 2008;

Hope *et al.*, 2006). Similarly, faunal distribution is positively related to proximity to natural habitats and corridors, which provide a link between fragmented habitat areas within the city (Germaine *et al.*, 1998; Daniels and Kirkpatrick, 2006; Loss *et al.*, 2009). However, fragmentation between houses, neighborhoods, or land use types introduces the urban equivalent of “ecotones” – transition zones between pavement and yard, or a lawn and a garden, or a park and a commercial mall. The preponderance of edges in a highly fragmented landscape increases the abundance of edge-dwelling species and decreases the abundance of those species particularly sensitive to edge effects.

Cities and Their Hinterlands

City-scale decisions about land use can act as “top-down” controls on biodiversity by constraining the spatial patterns of land use or through ordinances on land use and land management practices (e.g., limitations on lawn watering). City-scale decisions also affect smaller, localized areas of land owned and managed by the city, such as parks and public right of ways, as well as habitats that are less frequently managed by individuals, such as rivers and canals. Finally, cities are surrounded by nonurban land, their “hinterlands,” on which they can exert influence and from which urban residents may obtain certain ecosystem services. Variation of management practices and regulations among cities is driven by some of the same considerations as those of individuals (such as wealth and culture). However, the influence of city-scale decisions on biodiversity is also constrained by the environment itself, for example, topography, climate, and availability of water resources.

As noted earlier, the ecosystem services that are needed by city residents include provisioning services (e.g., food, fuel, water, and building materials); cultural services (including city “identity” and recreational opportunities for urban residents); and regulating services (such as flood, water quality, disease, and fire control). Some of these services are provided within a city, such as recreation in urban parks, food provisioning by urban agriculture, climate regulation by urban green space, and waste (nutrient) removal by wastewater treatment plant microorganisms. Other services are obtained via connections with urban hinterlands: water supply may be obtained through protecting a city’s watershed, recreational opportunities also exist outside of a city, and waste is often disposed of outside of a city’s borders (e.g., wastewater delivered downstream, landfills, and deposition of air pollutants downwind). Although cities often do not have jurisdictional control over their hinterlands, they do exert indirect control as a strong center of resource consumption and demand for ecosystem services. Finally, the way in which cities control services can impact plant and faunal distribution patterns. Many cities employ technological or hard engineering approaches to provide certain services, whereas other cities rely more heavily on green infrastructure (Gill *et al.*, 2007; Tzoulas *et al.*, 2007). For example, stormwater management ranges from hard engineering, such as pipes or concrete structures, to green infrastructure such as multiuse floodways, retention basins, and rain gardens. This example illustrates that how a city provides

services has a potential impact on habitats and biodiversity within and around the city.

Decisions and actions taken at the city level can also have direct impacts on urban species composition especially through management of city-owned property. Urban protected areas, such as urban forests, often house and protect native vegetation. Parks and gardens have mixes of native and non-native vegetation. These areas are often managed to provide certain services to residents, such as playing fields, space for vegetable gardens, or decorative flower gardens and arboretums. The selection of species and resulting species composition is dependent on these goals. Although plant diversity in parks is directly controlled by city managers, diversity of other taxonomic groups may be strongly influenced by the surrounding land use and socioeconomic factors such as wealth (Kinzig *et al.*, 2005). Cities can also have “top-down” control on residential decisions about their own properties, for example, by banning certain plants such as cottonwood and olive trees, for health concerns.

Cities impact species composition indirectly both within and beyond city boundaries through connections with agricultural areas that supply food to the city and recreational areas used by urban residents. Urban demand for certain food can drive crop selection by farmers. Recreational use of public lands by urban residents may alter species composition through the transport of invasive (and native) species by boats and cars (Hansen and Clevenger, 2005; Rothlisberger *et al.*, 2010). Finally, as cities expand, biodiversity is directly impacted by new development and changing land uses (McDonald *et al.*, 2008).

The spatial pattern of parks, public right of ways, and stream corridors is often very important in terms of how much habitat is available for higher trophic levels such as birds, reptiles, amphibians, and mammals. Park size can matter greatly for large animals with greater territory needs. Furthermore, although avian diversity is often related to socioeconomic patterns at the neighborhood scale (Kinzig *et al.*, 2005), other studies have found that avian diversity is also affected by the plant diversity of streetways and parks (White *et al.*, 2005; Sandstrom *et al.*, 2006). Some species thrive in the urban landscape. Plants whose seeds are carried along roads by wind or in the tread of vehicles do not face a fragmented landscape, but a highly connected one (Hansen and Clevenger, 2005). In contrast, fragmentation of suitable habitat is often dangerous for species that migrate seasonally between habitats, such as amphibians during breeding season.

The availability of resources, such as food, nutrients, and water, are often greatly varied by decisions made at the city scale. At the city scale, many of these altered resource flows are intentional, though only indirectly related to biodiversity. For example, imported food eventually ends up in wastewater, dramatically increasing nutrient availability in downstream ecosystems (Lauver and Baker, 2000; Baker *et al.*, 2001). However, storage of water for human use in reservoirs reduces the availability of water to downstream systems and creates new freshwater habitats upstream of cities.

As dense areas of human settlement, cities have large populations and property to protect from disturbances such as floods and fires (Radeloff *et al.*, 2005). With active and effective management, these disturbances can often be reduced within cities. However, cities also provide new human

sources of fire, and the built environment is especially prone to flooding due to altered hydrology (Paul and Meyer, 2001). Some management of disturbances in cities may only displace disturbances elsewhere. For example, stormwater drainage reduces flood damage within cities, but drastically changes the hydrology and disturbance regimes of downstream ecosystems. This has led to a reduction in species richness of fish and invertebrates in many areas (Paul and Meyer, 2001). However, prevention of disturbances may negatively impact disturbance-adapted species.

Networks of Cities and Their Hinterlands (Regional and Global Scales)

Although city officials, neighborhood associations, and individuals determine many features of individual cities, cities are located within a complex web of interconnected metropolitan areas and nonurban ecosystems. Although fewer decisions are directly made at this regional or global network scale, it is important to note some of the emergent functions of these networks and the effects they might have on biodiversity at the city scale and globally. Unlike cities and individuals, networks of urban areas rarely have goals or ecosystem services that they are intentionally and collectively pursuing (although note the emergence of networks of city mayors, such as the US Conference of Mayors Climate Protection Agreement, planning together for climate change adaptation). Instead, one can think of networks of cities as a scale at which the effects on biodiversity are primarily unintentional and indirect. A fundamental function of city networks is to redistribute goods, resources, species (including diseases), and people between cities separated by great distances. Thus, cities are connected specifically through the exchange of goods, people, and ideas. Finally, cities can act as regional centers of consumption, and therefore can indirectly affect land management and biodiversity in regions that produce goods and services for the city (Luck *et al.*, 2001).

Resources such as nutrients are redistributed globally and regionally through trade networks. A key example is the global fertilizer trade that provides nutrients and resources needed to grow and support a variety of crops at regional, city, and local scales (Cordell *et al.*, 2009). Global networks of cities also profoundly affect biodiversity via the intentional and unintentional movement of species (Levine and D'Antonio, 2003). Landscaping and ornamental plants are perhaps the most common intentionally traded species within the urban context, but animals are also intentionally introduced to urban areas, such as starlings and ornamental fish (Whittington and Chong, 2007). Trade in species clearly affects the biodiversity of the cities importing new species, but it may also negatively impact biodiversity in the exporting region if that species is threatened or endangered. Although there are various national and international agreements and legislation regarding the sale of endangered species, illegal markets still exist.

The effects of intentional movement of species might be insignificant compared to the effects of unintentional species transport around the globe. These effects are felt primarily through the movement of invasive species and diseases. Aquatic invasives are transported largely through shipping (Hulme, 2009), and therefore primarily affect port cities.

Terrestrial invasives, however, easily travel along roadways, transported by wind or in the treads of vehicles (Hulme, 2009). Animal and plant diseases can easily spread from city to city inadvertently through trade, much of which is inadequately monitored to prevent disease spread (e.g., Whittington and Chong, 2007). Some connections between disease and biodiversity cover long distances and complex market relationships (e.g., relationships between Bovine Spongiform Encephalopathy (BSE) in the UK and the abundance of North American grassland birds; Nocera and Koslowsky, 2011).

Finally, the movement of people around the globe and subsequent shifts in local demographics and culture is another significant way in which the connections between cities can constrain or alter local patterns of biodiversity. Immigration to cities can have substantial effects on urban biodiversity due to cultural changes especially with regard to landscaping preferences. In fact, increasingly, the flora and fauna of cities are becoming more homogeneous within the US and globally (McKinney, 2006).

Applying and Testing Ecological and Social Theories in Urban Systems

It has been argued that studying ecology and biodiversity in cities is essential because this is where most people live – and thus we need to understand the relationship between human activities and ecosystem services in the urban biosphere and its impact on human well-being. But there is a second scientifically driven reason to study biodiversity: it offers us a chance to test ecological theories, and to ask whether our theories, developed in more pristine (less human-dominated ecosystems), apply when humans dominate the system (Collins *et al.*, 2000). Do our theories – about how species assemblages change, interact, scale with area, transform resource flows, and withstand disturbance regimes – hold when we have biotic communities almost “haphazardly” assembled (from an ecological perspective), and with no coevolutionary history? To what extent can humans – themselves the product of evolution – be treated as “just another species” in the ecosystem, and when do we need new theories – borrowed from the social sciences or synthetically created across disciplines – about human behaviors and their influence on ecological systems?

Arguing from first principles, one could assert that ecological theory should continue to apply. Humans are, after all, “just another species,” the product of evolutionary processes. Analogs of many human activities – species consumption and dispersal, “fertilizing” of patches through waste disposal, and disturbance through fire or “grazing” (mowing) – can be found among the nonhuman species with whom we share the planet.

Consider, for instance, the use of a “gradient approach” for assessing biodiversity patterns in urban settings. Many studies examine the relationships between biodiversity and certain indicators of human pressure, activity, or disturbance along an urban to rural gradient – indicators such as population density, percent impervious surface, or distance from urban center (Blair, 1999). One assumption implicit in this approach is that the characteristics of the individuals occupying the space – their preferences and the capacity to realize those preferences – matter very little to outcomes. We need to only

know how closely they are packed together (population density), or their preference for urban or suburban landscapes (distance from city center), or their propensity for spreading to know what impact they will have on biodiversity. This approach is consistent with current ecosystem- and community-ecological theory, which primarily tends to treat humans as an exogenous perturbing force on the landscape (or ignore them completely). In other words, relying only on current theories we need primarily to know something about the magnitude of disturbance inflicted, or the gross flow of mobilized resources, to understand the impact humans will have on biodiversity outcomes. This suggests, for example, that a thousand “snowbirds” (transplants from the Midwest) living in a square kilometer on the fringe of Phoenix should have the same impact on biodiversity as 1000 Guatemalan refugees living in the same area. This seems unlikely, given what we have discovered over the past decades about human interactions with urban ecosystems – and indeed the environment more generally (see, e.g., Warren *et al.*, 2010; Hegmon *et al.*, 2008). Groups of different ages or cultural backgrounds prefer different landscapes and value different ecosystem services. In addition, socioeconomic status will enable or constrain the capacity to realize those landscapes. To build on this example and the idea of testing and adapting existing theories – both social and ecological – to address urban systems, the authors provide a brief history of urban ecology.

The study of cities from an ecological perspective in the US began with the Park *et al.* landmark 1925 publication, *The City* (Park *et al.*, 1925), which formally introduced human ecology as a new research agenda for sociology and the study of cities in America. Their research focused on many social changes that were a result of rapid expansion of America’s urban areas due to the mass immigration of people from Europe and rural America. The explosive growth of the city, the confluence of people from diverse backgrounds, the breakdown of old ways, and the changes that were necessary for a viable new urban life caught the imagination of the authors.

Although Park *et al.* drew on the work of European social and biological scientists, such as Malthus, Darwin, and Spencer, the initial development of human ecology in America was influenced significantly by and contemporaneous with the emerging fields of plant and animal ecology in America. The Chicago School – as it came to be known – conceived of human ecology as an extension of the developing fields of plant and animal ecology.

The Chicago School articulated and developed an approach to human ecology that drew on and paralleled earlier ecological work. First, Park and his colleagues applied a community ecology approach to the complexities of urban society in order to uncover a set of regular social patterns and processes in the apparent confusion of the urban melting pot. For instance, Park *et al.* employed ecological concepts such as succession, competition, and metabolism to describe stages of human community structure (organization) and function (processes): specifically, indicators of social disorganization such as disease, crime, vice, insanity, and suicide. Second, the Chicago School conceived of the city as a closed and functional system (community) that could be treated as an organism or “superorganism.” Park and his colleagues also focused on the spatial and temporal dimensions of the city.

A significant product of this work was Burgess’ ideal model of the city which the Chicago School used to describe and measure the city’s spatial differentiation and development into zones and areas-within-zones through processes of concentration, centralization, segregation, invasion, and succession.

The Chicago School’s conception of human ecology was criticized strongly by social scientists for several reasons, including opposition to the use of biological factors to explain individual human behavior and social structures; a singular reliance on competition as the mechanism for explaining the organization of economic functions and the spatial distribution of human populations and services; and the use of macroscale processes and functional approaches to explain individual behavior from both a conceptual and a statistical point of view. Many of these criticisms were addressed in later studies in human ecology.

As in the example of the “snowbirds” and Guatemalans, it is not enough to treat humans or human ecological systems as monolithic blocks. Just as performance tradeoffs and the emergence of different strategies for resource acquisition and reproduction can influence the patterns of biodiversity on the landscape, differences in the structure and organization of human social systems need to be considered in order to understand how humans impact and manipulate the biodiversity surrounding them.

All social species are characterized to varying degrees by patterns and processes of social differentiation. In the case of *Homo sapiens*, social differentiation or social morphology has been a central focus of sociology since its inception. In particular, social scientists have used concepts of social identity (age, gender, class, caste, and clan) and social hierarchies (wealth, power, status, knowledge, and territory) to study how and why human societies become differentiated.

Social hierarchies – or social differentiation – is an important concept for understanding human ecological systems because it affects the allocation of critical resources (natural, socioeconomic, and cultural) and hence the patterns of and impacts on biodiversity. In essence, social differentiation determines “who gets what, when, how, and why.” This allocation of critical resources is rarely equitable. Unequal access to and control over critical resources is a consistent fact within and between households, communities, regions, nations, and societies.

Wealth is access to and control over material resources in the form of natural resources, capital (money), or credit. The unequal distribution of wealth is a central feature of human ecological systems, and one that must be accounted for when examining the driving forces behind past changes in the environment and predicting the impacts of future policies and conditions. Power is the ability to alter others’ behavior through explicit or implicit coercion. The powerful (often elites with political or economic power) typically have access to resources that are denied to the powerless. Status is access to honor and prestige and the relative position of an individual (or group) in an informal hierarchy of social worth. Status is distributed unequally, even within small communities, and high-status individuals may or may not have access to either wealth or power. For instance, a minister or an imam may be respected and influential in a community even though he or she is neither wealthy nor has the ability to alter coercively other people’s behavior. Knowledge is access to or control over

specialized types of information (technical, scientific, religious, and so forth). Not everyone within a social system has equal access to different types of information. Knowledge often provides advantages in terms of access to and control over the critical resources and services of social institutions. Finally, territory is access to and control over critical resources through formal and informal property rights.

These types of hierarchies – or differentiation – are important constraints that affect the allocation or supply of critical resources. It is also important to examine and understand variations in demand. For instance, additional social characteristics that may affect the demand for critical resources are often related to demographics or ethnic or religious backgrounds, since different age groups and various cultures may have different needs from, or attitudes toward, their environment and each other.

Social differentiation within human ecological systems also has a spatial dimension that is usually characterized by patterns of territoriality that lead to spatial heterogeneity on many scales. A spatial understanding of social differentiation in an ecological context enables researchers to ask “who gets what, when, how, why, and where?” and subsequently, to ask about the reciprocal relationships between spatial patterns of sociocultural and biophysical patterns and processes of a given area (Grove and Burch, 1997).

Today, it is increasingly difficult to determine where traditional biogeophysical ecology ends and human ecology begins (Golley, 1993). The articulation of a biosocial approach to human ecological systems has occurred over the past 20 years. Importantly, this approach is continuously advanced by the development of and discourses between theories related to plant, nonhuman animal, and human ecologies and social sciences. Indeed this integration among ecological and social sciences is absolutely essential if we are to understand the functioning and dynamics of cities in an ecological landscape, and if we are to be able to both understand and predict the impacts of humans in urban centers on biodiversity.
